Journal of Volcanology and Geothermal Research
Explosive Glaciovolcanism at Cracked Mountain Volcano, Garibaldi Volcanic Belt, Canada
--Manuscript Draft--

Abstract:	Cracked Mountain (CM) is a basaltic volcano within the northern extension of the Cascade volcanic arc into southwest, British Columbia, Canada (i.e. Garibaldi Volcanic Belt) and is dated at 401 ± 38 ka (^{40}Ar/^{39}Ar). The edifice covers an area of ~1.5 km^2 and has a volume of 0.18 km^3. The volcano features steep margins with local relief of ~250 m (1,650 m a.s.l), is dissected by abundant 0.5 to ~20 m wide extensional cracks with depths up to 30 m, and has a highly eroded top. The edifice is dominated by massive to poorly stratified, moderately to pervasively palagonitized lapilli tuffs, comprising vitric fine ash to lapilli. Juvenile pyroclasts have blocky to highly vesiculated shapes consistent with a phreatomagmatic (i.e. explosive) origin. The lapilli tuffs are intruded by and mingled with coherent to disaggregated lobes of peperitic pillowed lavas. Contacts between lapilli tuff and peperitic pillowed lava show soft-sediment deformation and in-situ quench-fragmentation indicating that the tephra was both unconsolidated and water-saturated at the time of intrusion. Local stacks of pillow lava are found on the margins of the edifice. More than fifty, 0.5 to 3 m wide dykes intrude CM stratigraphy and display, either, peperitic pillowed margins or sharp, chilled margins and columnar-jointing. Measurements of paleomagnetic directions (9 sites) were made for all CM lithofacies and record a single-pole direction indicating a single monogenetic eruption. A glaciovolcanic origin is strongly suggested by the abundant subaqueous lithofacies (i.e. palagonitized tephra, pillows, peperites) and the physiographic setting of the edifice which is well above any drainage that could sustain a standing body of water. The elevation of CM and depth of surrounding valleys indicate syn-eruptive confinement by a paleo-ice sheet that was ≥ 850 m thick. The edifice shape, size, and surrounding topography suggest a 'leaky' paleolake system capable of supporting ~0.36 km^3 of water. The glaciovolcanic origin and the absolute (^{40}Ar/^{39}Ar) age of CM represent an important record of the Cordilleran Ice sheet (CIS) in southwestern BC during the mid-Pleistocene.

JVGR Editorial Board
Journal of Volcanology and Geothermal Research
Elsevier Editorial System

To the Editorial Board,

This letter is to accompany our revised manuscript: "Explosive Glaciovolcanism at Cracked Mountain Volcano, Garibaldi Volcanic Belt, Canada" submitted to the Journal of Volcanology and Geothermal Research for publication as a Research Paper. The manuscript is authored by me (Martin Harris), Kelly Russell, Rene Barendregt, Lucy A. Porritt, and Alexander Wilson and is an original unpublished research article and is not under review, elsewhere.

The original submission was reviewed by Dr. Rosie Cole, who provided feedback in the form of minor comments. The manuscript was also reviewed by the JVGR editor Jim Gardner, who provided constructive feedback on ways to improve the flow and presentation of information. We have essentially accepted and incorporated all comments from both reviewers. Additionally, we have gone through the entire document, including text, figures, and tables, and moderately revised portions for clarity and to reduce redundancies. The details of these revisions can be found in our response to the editor document. Our submission includes our manuscript (with changes tracked and a clean version provided), 14 figures, and 3 tables, accompanied by 3 supplements (containing 2 figures and 3 tables). The word count is ~6400 words (from introduction to summary).

Our work contributes to the field of glaciovolcanism. Few studies have identified explosive onsets to glaciovolcanic eruptions making the deposits found at Cracked Mountain unique within the existing literature. We think these results will be of interest to, both, volcanologists and paleoclimatologists. We believe publication in JVGR offers us an appropriately broad and international readership.

Below is a list of potential referees for this manuscript who we feel would be interested and willing to provide a timely and impartial evaluation of the merits of our work:

Ben Edwards –Earth Sciences, Dickinson College, Carlisle, PA, USA; edwardsb@dickinson.edu
Ian Skilling –Geology, University of South Wales, Pontypridd, United Kingdom; ian.skilling@southwales.ac.uk
Brittany Brand –Geosciences, Boise State University, Boise, ID, USA; brittanybrand@boisestate.edu.
Pierre-Simon Ross – Institut national de la recherche scientifique, Quebec City; pierre-simon.ross@ete.inrs.ca
Catherine Hickson – Tuya Terra Geo Corp, Vancouver, Canada, ttgeo@telus.net
Melanie Kelman –Geological Survey of Canada, Vancouver, Melanie.Kelman@nrcan-rncan.gc.ca.

Thank you in advance for your consideration.
Sincerely,

Martin Harris

Manuscript Number: VOLGEO-D-21-00262   Response to Reviewers

Reviewer #1: Review of Harris et al: "Explosive volcanism at Cracked Mountain Volcano, GVB, Canada"
JVGR
Rosie Cole

This manuscript provides a glaciovolcanic eruption and emplacement model for the Cracked Mountain edifice, based dominantly on detailed field evidence. It is a great contribution of an explosively formed edifice with intrusive and peperitic bodies. Paleomagnetic field directions derived from all units are used to support a continuous eruptive history. The study provides a constraint on the thickness of the continental ice sheet at the time of eruption. It is a good example of how glaciovolcanic sequences can be used as paleoenvironmental indicators.

The manuscript gives fantastic detailed field descriptions of each lithofacies. The lithofacies associations make the relations between different rock types clear. Interpretations are justified and supported by relevant evidence. It is great to see additional paleomagnetic evidence which supports the eruption model. The text is also well structured and written, and the figures are clear and informative. My comments are minor:

Line 49: Can you briefly explain what the Mosaic Assemblage is?
Author response: We have elaborated in the text what the Mosaic Assemblage is defined as (line 47 in revised text).

Line 161: What is a blooming dyke?
Author response: We have expanded this sentence to include a description of what I mean by 'blooming' dyke (line 155 in revised text)

Line 164: Unfinished sentence, but peperite is defined with White and Houghton reference above, so it isn´t necessary here.

Author response: We agree with this comment and this sentence has been removed.

Line 182: "Commonly glaciated" suggests a glacier still sometimes accumulates here. Do you mean that at one time a glacier has over-ridden this lava to make striations and deposit erratics?

Author response: We have removed 'commonly glaciated' as I agree it can be misconstrued. I have revised the sentence to clarify that the tops of the lavas are scoured by past cycles of glaciation and that erratics now sit on top (line 171 in revised text).

Line 199: You mention that the source of the deposits is higher up - can you say where the vent(s) was? What was the relationship between the vent and the ice? Have these deposits travelled under ice from the vent or have they met ice further away from the eruption site?

Author response: We have added a couple of clarifying sentences at the start of subsection 5 (line 184 in revised text), which add more information on our understanding of vent location and any evidence of magma-ice contacts.

Line 282: Which rocks were these samples taken from for chemical analysis? Can you explain the spread in chemistry shown by the TAS diagram? Is there a relationship between the chemistry and the inferred phase of eruption, for example?

Author response: We have added a clarifying sentence (line 267 in revised text) to address which volcanic units were used for whole-rock chemistry. I have expanded the end of the second paragraph (line 276 in revised text) in this section to explain possible reasons for the spread of TAS and how it relates to stages of the eruption.

Line 553-560: Is there any other evidence from the region that you can use to support this estimate for ice thickness at this slightly older date or during MIS 12?

Author response: We have revised parts of the text (lines 479-501 in revised text), to provide more regional evidence of volcanism during MIS 12. Although no other dates exist that can support our ice thickness models, there are a few older studies that indicate the presence of, or absence, of glacial ice in SW British Columbia at this period in the Pleistocene. I have cited an additional study to support these additions.

Line 578: intrusive and effusive styles?

Author response: We have changed this sentence to say 'intrusive and effusive activity (line 518 in revised text).

Figure 1: label all features mentioned in geological background text.
Author response: We have revised this figure to include additional features mentioned in the geological background, including the explorer plate, Salal Glacier, Elaho valley, Mosaic Ridge, Lillooet Ridge.
Figure 2: - Log 5 is shown in the granodiorite
- Lithologies legend, second down - check spelling of coherent.
- Third down - what is lava tuff?

Author response: We have moved the Log 5 location to be at the edge of the edifice, and corrected the spelling of coherent, and added the work breccia that was previously missing. Additional reformatting was also done on this figure to increase font sizes and improve readability.

Figure 3: not easy to see the cracks here - can they be emphasised or can some be annotated?

Author response: We have added another google earth image, now 3B, that better shows the cracks that run through the whole volcano.

Figure 11: Can you show the Maximum Angular Deviation (MAD3) on these plots? Is the ambient regional paleomagnetic field direction for this area and time known? If so, it should be stated and shown for comparison on the stereoplot. Is it consistent with the direction shown for these deposits? This would give confidence to both the age estimate and the assumption that there has been no rotation.

Author response: MAD values have been added as suggested by the reviewer. GAD (Geocentric Axial Dipole field directions) and PEF (present earth's field directions) for sampling locality have now been added to TableC1 and Fig. 11, as suggested by the reviewer. The mean direction for sites is within expected secular variation (see mean of sites 2-9 and GAD inclination for sampling latitude, Fig. 11 and Table C1. Additionally, reported values have been adjusted to the tenth decimal place (rather than the hundredth) to better represent the precision of the paleomagnetic results. Lastly, in Fig 11B, we replaced sample CMV60 with CMV15, which is of the same lithofacies (Lt1) but better reflects the differences observed between AF demagnetization and thermal demagnetization.

Figure 12D: typo in edifice?

Author response: This figure has been revised so that the text has been removed to limit the presentation of redundant information. We feel there is an adequate explanation of the stages of the eruption in the text and figure caption and is not needed in the figure itself.

Other Modifications:

We have revised the text moderately for clarity and brevity. Subheadings of lithofacies and lithofacies associations have been removed to make the manuscript less choppy, as suggested by the editor Jim Gardner.

The discussion section has been reorganized and revised into two sections (rather than four in the previous version). This decision was made to reduce the repetition of information and focus on our major findings and implications. Section 8.1 is now 'Explosive Onset to Glaciovolcanic Eruption'. This section contains our detailed evidence for the explosive eruption at Cracked Mountain which makes it a unique glaciovolcanic eruption worthy of documentation. The end of section 8.1 contains the abbreviated eruptive succession (depicted in figure 12) after the explosive onset. Section 8.2 is now 'Paleoenvironmental implications'. This section presents our evidence-based modelling for a reconstructed cordilleran ice-sheet extent and timing within the mid-Pleistocene. Here we drive home the importance of our investigation of Cracked Mountain volcano as a land-based proxy that can be used to inform on the paleoclimate of SW British Columbia.

Figures 10A and B have been modified so that their x-axis (SiO_2 wt %) are in the same range. Fig 10C has been modified, and now data are normalized to a Chondrite, as we feel this is more conventional with other literature.

Figure 13 has been revised for readability with larger text and less white space.

Figure 14 has been revised with an indication of our 'preferred' age of 425 ka as a dashed line.

Tables 3, A1, and A2 have been revised to include 2s analytical precision values, and all values are now reported to their significant digits.

Appendix Fig A1 has been removed as we no longer feel it is necessary, as the data can be presented in table format.

Explosive Glaciovolcanism at Cracked Mountain Volcano,

Garibaldi Volcanic Belt, Canada

Abstract

Cracked Mountain (CM) is a basaltic volcano within the northern extension of the Cascade volcanic arc into southwest, British Columbia, Canada (i.e. Garibaldi Volcanic Belt) and is dated at 401 ± 38 ka (^{40}Ar/^{39}Ar). The edifice covers an area of ~1.5 km^2 and has a volume of 0.18 km^3. The volcano features steep margins with local relief of ~250 m (1,650 m a.s.l), is dissected by abundant 0.5 to ~20 m wide extensional cracks with depths up to 30 m, and has a highly eroded top. The edifice is dominated by massive to poorly stratified, moderately to pervasively palagonitized lapilli tuffs, comprising vitric fine ash to lapilli. Juvenile pyroclasts have blocky to highly vesiculated shapes consistent with a phreatomagmatic (i.e. explosive) origin. The lapilli tuffs are intruded by and mingled with coherent to disaggregated lobes of peperitic pillowed lavas. Contacts between lapilli tuff and peperitic pillowed lava show soft-sediment deformation and in-situ quench-fragmentation indicating that the tephra was both unconsolidated and water-saturated at the time of ~~magma~~ intrusion. Local stacks of pillow lava are found on the margins of the edifice. More than fifty, 0.5 to 3 m ~~thick~~wide dykes intrude CM stratigraphy and display, either, peperitic pillowed margins or sharp, chilled margins and columnar-jointing. Measurements of paleomagnetic directions (9 sites) were made for all CM lithofacies and record a single-pole direction ~~(i.e. within uncertainty)~~ indicating ~~that the edifice likely represents~~ a single monogenetic eruption. A glaciovolcanic origin is strongly suggested by the abundant subaqueous lithofacies (i.e. palagonitized tephra, pillows, peperites) and the physiographic setting of the edifice which is well above any drainage that could sustain a standing body of water. The elevation of CM and depth of surrounding valleys indicate syn-eruptive confinement by a paleo-ice sheet that was $\geq$ 850 m thick. The edifice shape, size, and surrounding topography suggest a 'leaky' paleolake system ~~was~~ capable of supporting ~0.36 km^3 of water. The glaciovolcanic origin and the absolute (^{40}Ar/^{39}Ar) age of CM ~~represents~~represent an important record of the Cordilleran Ice sheet (CIS) in southwestern BC during the mid-Pleistocene.

Key Words: Glaciovolcanism, Subglacial, Phreatomagmatic, Basalt, Englacial Lake, Ice-Sheet

1. Introduction

The Garibaldi Volcanic Belt (GVB) is the northern segment of the Cascade Volcanic Arc (Roddick and Souther, 1987; Green et al., 1988; Hildreth, 2007). GVB volcanic deposits range from Pleistocene to Holocene in age and result from subduction of the Juan de Fuca plate beneath the North American Plate (Roddick and Souther, 1987; Green et al., 1988; Hildreth, 2007). Southwest British Columbia has a protracted history of multiple glaciations, with cycles of advancing and retreating ~~continental~~cordilleran ice sheets throughout the Pleistocene (Clague, 2009; Clague and Ward, 2011). As a result, the GVB hosts numerous glaciovolcanic landforms. Prior studies concerning glaciovolcanism have focused on the Mount Garibaldi volcanic field (e.g., Mathews, 1952; Wilson et al., 2019), the Mount Cayley volcanic field (e.g., Kelman et al., 2002; Kelman, 2005), the Mount Meager volcanic complex (MMVC) (e.g., Wilson and Russell, 2017, 2018), the Salal Glacier volcanic complex (e.g., Lawrence et al., 1984; Wilson and Russell, 2018), and the Bridge River volcanic field (e.g., Roddick and Souther, 1987; Wilson and Russell, 2018).

Cracked Mountain is a ~~~0.18 km³~~ basaltic volcano situated on the southern flank of the MMVC and originally identified by Read (1979) as part of the Mosaic Assemblage~~.~~ (i.e., undivided, Pleistocene aged, basalts within the MMVC). Here, we present a new dataset including a map of volcanic lithofacies, petrographic and geochemical characteristics of the deposits, geochronometric (^{40}Ar /^{39}Ar) age estimates, and paleomagnetic directions of all lithofacies. Collectively, these data inform on the physical volcanological evolution of the Cracked Mountain (CM) volcano. Our analysis shows CM to have a glaciovolcanic origin (Kelman et al., 2002; Smellie, 2007; Edwards et al., 2009) involving sustained eruption within an englacial lake. The lithofacies and their stratigraphic relationships indicate an explosive onset to the eruption ~~onset~~ dominated by phreatomagmatic activity that transitioned to effusive ~~eruption~~activity expressed by intrusions and lavas. We use the geometry of the CM edifice (i.e. shape and size) and the distribution of lithofacies to reconstruct the eruptive history of the glaciovolcanic edifice and to constrain the ~~minimum~~ thickness and distribution of the enclosing ~~paleo~~-ice sheet. Our findings contribute to a larger story of glaciovolcanism within the GVB and ~~understanding the~~ paleoclimate ~~of~~reconstructions for SW British Columbia.

2. Geological Background

The Mount Meager volcanic complex is situated 160 km north of Vancouver in SW British Columbia (Fig. 1) and is one of eight major centres and volcanic fields comprising the GVB (Fig. 1A). Recent GVB geochemical and petrological studies show increases in melt alkalinity and a decrease in slab-derived signatures moving northward in the GVB (Green and Sinha, 2004; Mullen and Weis, 2013). In particular, the MMVC, Salal Glacier volcanic complex, and Bridge River volcanic field show a heightened primitive signature compared to the southward GVB and the High Cascade volcanoes. These findings suggest that the Nootka Fault, located Northwest of the Bridge River cones (Fig.1A), may mark the terminus of the Juan de Fuca subduction where a window between the Juan de Fuca and Northward Explorer plate allows upwelling of asthenospheric melts under the northernmost GVB centres (Mullen and Weis, 2013).

The MMVC (Fig. 1B) contains Pleistocene to Holocene basalt to rhyolite overlying basement igneous and metamorphic rocks of the Coastal Plutonic complex (Fig 1B) (Woodsworth, 1977; Read, 1979; Green et al., 1988). The MMVC is also host to the youngest GVB eruptive deposits, namely the 2350 B.P. Pebble Creek formation (Hickson et al., 1999; Stewart et al., 2008). Intermediate to felsic lavas are dominant within the Mount Meager Massif, however, localized mafic centres are present in the north (Lillooet Ridge and River), west (Mosaic Ridge), and southwest (Cracked Mountain and Elaho Valley) regions of the volcanic complex (Fig. 1B) (Read, 1979, 1990; Harris and Russell, 2021). The ages of the Mosaic Ridge basalts and Elaho Valley basaltic andesites are ~90 and 140 ka respectively (Woodsworth, 1977; Green et al., 1988).

3. Cracked Mountain Physiography and Morphology

The Cracked Mountain volcano unconformably overlies basement granodiorite (Bg) and schist (Bs) of the Gambier and Cadwallader Groups respectively (Fig. 2A) (Read, 1979). The volcanic deposits form a slightly asymmetric, NE-SW trending ~250 m thick ridge that is ~1,300 m long and ~1,000 m wide, covering an area of ~1.5 km^2 and having a present-day volume of ~0.18 km^3. The summit of CM rises to 1,650 m above sea level (a.s.l.) and the margins reach elevations as low as 1,250 m (Fig. 2A). CM is surrounded by steep valleys of the Meager Creek

94 and Elaho River tributaries to the north and west respectively (Fig. 3). Extensional cracks dissect

95 the entirety of CM (Figs. 2A; ~~3A~~3B), ranging from 0.5 to > 20 m in width and up to 30 m in

96 depth. The fractures form parallel clusters that commonly trend perpendicular to the downslope

97 direction. All CM lithofacies are offset and displaced by cracks. No glacial deposits (i.e. till,

98 erratics) are found within cracks, suggesting a post-eruptive and post-glacial origin.

99   The shape and surface features of CM show evidence of glacial enveloping and scouring.

100 The present-day surface is littered with cobble to boulder-sized granitic erratics and some

101 locations have been smoothed and striated in a SW direction. These findings show that post-

102 eruption Cordilleran Ice Sheets have reached elevations greater than the summit of CM. The

103 margins of CM are cliffs up to 40 m high, which is unusually thick for basaltic lava (e.g.,

104 Edwards et al., 2015). We interpret this morphology to be a result of syn-eruptive glacial

105 confinement and subsequent erosion. There is no evidence of ice-abutment in the form of

106 laterally facing, hackly, or irregular jointed lavas (e.g., Lescinsky and Fink, 2000; Kelman et al.,

107 2002) suggesting that the outermost CM margins result from post-eruptive glacial erosion rather

108 than reflecting primary lava-ice contact surfaces.

109

4. Volcanic Lithofacies

111   We recognize ten CM lithofacies (Table 1) that include, both, volcaniclastic and coherent

112 lithofacies. All volcanic deposits are olivine and plagioclase porphyritic and differ only in their

113 groundmass textures ranging from holocrystalline, hypocrystalline, and quenched. The

114 terminology used to describe grain size and componentry of volcaniclastic rocks is after White

115 and Houghton (2006).

116

117 4.1 Volcaniclastic

118 ~~4.12 Lapilli Tuff (Lt$_{1-3}$)~~

119   CM lapilli tuffs (Lt$_{1-2}$) (Table 1) form the stratigraphically lowest (Fig. 2B) lithofacies.

120 Observed thicknesses range from 0.5 m to < 6 m. Lt$_1$ is massive, moderately- to poorly sorted,

121 and is observed throughout the CM edifice from its base to its summit (Fig. ~~2A~~2; 4A). Lt$_1$ is

122 ~~comprised~~composed of dense and blocky to highly vesiculated and cuspate vitric juveniles and

123 contains 5-35% lapilli-sized clasts supported in a vitric ash matrix. Lt$_1$ is commonly intruded by

124 dykes (Ld$_{1-2}$) and mingled with peperitic lobes (Lpi; Table 1) (Fig. 5). In some locations, soft-

125 sediment deformation of Lt_1, in the form of squeeze-up pipes, is observed. Lt_2 outcrops in the SE

126 and N sections of CM and, by comparison, are thinly bedded, well-sorted (Fig. 4B). Beds of

127 ultra-fine ash are up to 5 cm thick and dip shallowly in the downslope direction. In some

128 outcrops, microfractures offset laminated beds, and truncated and shallow cross-beds are also

129 observed. Lt_2 is commonly observed as 1-2 m layers within thicker, massive Lt_1 exposures (Fig.

130 2B; 4B) and displays fining upward grain sizes. Lt_3 are locally stratified as defined by

131 accumulations of lapilli and bomb-sized, fluidal to blocky, vesiculated (<60%) spatter clasts

132 (Fig. 4C). The clasts are supported by a well-sorted, vitric ash matrix. Two small outcrops of Lt_3

133 are located at upper elevations (i.e. high in stratigraphy) in the central and NE sections of the

134 CM.

135

136 4.13 Peperite (Pi)

137 Peperite (Pi) deposits, as defined by White et al., (2000) and Skilling et al., (2002), are

138 volcaniclastic deposits resulting from the mingling of magma with wet, unconsolidated

139 sediments. At CM, peperites occur as fragmented, globular to blocky components of vitric basalt

140 supported by ash and lapilli tuff matrix (Figs. 2B; 6). Peperite deposits are distributed along the

141 margins of the peperitic intrusive bodies (Lpi). We distinguish lithofacies Pi from Lpi (Table 1)

142 as volcaniclastic and coherent, respectively. The thickness of peperites varies from a few cm to

143 2-3 m away from the margins of Lpi. Peperites rarely outcrop at the present-day CM surface but

144 are commonly exposed in cracks at all locations of the volcano.

145

146 4.14 Tuff Breccia (Tb)

147 Tuff breccias (Tb) blanket much of the topography in the central and north regions, are

148 the dominant map unit (Fig. 2), and obscure stratigraphically older volcanic lithofacies. At higher

149 elevations, tuff breccias form thin 1-2 m-thick deposits that progressively thicken (<10 m)

150 downslope (Fig. 7). Tuff breccias are massive and clast-supported, featuring monolithic lapilli-to

151 block-sized lithic components. These lithics are olivine-and-plagioclase porphyritic lava

152 fragments of Lpi, Ls, and Lp, where ~30-40% show rounded chilled margins. Minor yellow ash-

153 sized interstitial sediment is present between breccia clasts. Rarely, block and lapilli-sized,

154 rounded Lt_1 lithics are present (Fig. 7B).

155

156   4.2 Coherent

157   ~~4.21 Peperitic Pillowed Lava (Lpi)~~

158   The peperitic pillowed lava unit (Lpi) (Table 1) comprises coherent, mingled lavas that

159   intrude volcaniclastic deposits (Lt) across all elevations and locations of the edifice (Fig. 2). Lpi

160   is a mappable unit ~~and is distinguished~~distinct from coherent pillow lavas (Lp; Table 1) ~~where~~

161   ~~Lpi intruded saturated sediments and Lp~~ formed through subaqueous effusion. ~~Lpi is commonly~~

162   ~~exposed in cracks as~~The Lpi unit occurs where magma has been injected into water-saturated

163   sediments and forms massive globular bodies up to 15-20 m across and 10-15 m high, ~~comprised~~

164   ~~of~~comprising chilled, subrounded lobes (Fig. 5A and B). Additionally, Lpi is often associated

165   with 'blooming' dykes (Ld$_1$) (Fig. ~~5C).~~5C) that transition from ~0.5-1 m wide intrusions into <5

166   m wide, "pillowed" masses. Since Lpi intrudes and pillows into lapilli tuff (Lt) (i.e. host

167   sediments) we interpret these lithofacies to be 'peperitic' intrusions.~~ Here we use the adjective~~

168   "peperitic", after White and Houghton (2006)~~ which has a genetic connotation describing~~

169   ~~deposits resulting from intrusion and mingling of magma and unconsolidated.~~

170   ~~.~~

171   ~~4.22 Pillow Lava (Lp)~~

172   Pillow lava deposits (Lp) (Table 1~~) comprise individually stacked radial and quenched~~

173   ~~lobes,~~), makeup ~20% of the edifice, and are the dominant lithofacies exposed at the edges of

174   CM (Fig. 2). Pillow lava ~~outcrop~~outcrops at the present-day, high elevations of CM (Figs. 2A) as

175   1-3 m thick piles and increases to ~ 10-40 m thick along the cliffs at the outer edges of the

176   volcano (Figs. 2B; 8A and B). Individual pillows are bulbous, with diameters up to 50 cm (Fig.

177   8C). Interstitial quench-fragmented vitric sediment fills void spaces between intact pillows in

178   some outcrops (Fig. 9A). Large radial columnar jointed pods up to 3 m in diameter make up a

179   lesser amount of the lithofacies. Stratigraphically, Lp is overlain by tuff breccia (Tb), is cut by

180   dykes (Ld$_2$), and is observed to overlie outcroppings of lapilli tuff (Lt$_1$) at the base of the edifice

181   (Fig. 2B).

182

183   ~~4.23 Sheet Lava (Ls)~~

184   Blocky and columnar jointed remnants of sheet lava (Ls) (Table 1) are preserved at the

185   highest elevations of CM near the central and eastern regions (Fig. 2A). Sheet lava outcrops are

186   small, ranging from ~10-30 m across, and 1-2.5 m thick. The sheet lavas have coarse columnar

187 joints up to 0.4 m in diameter and occur at the present-day surface of CM. The tops of the sheet

188 lavas are ~~commonly glaciated as indicated~~scoured by SW trending glacial striae and covered

189 with erratics (Fig 8D).

190

191 ~~4.24 Dykes (Ld$_{1-2}$)~~

192 Over 50 dykes (Ld$_{1-2}$) intrude the CM volcano (Fig 2A). The dykes are predominantly

193 subvertical and have widths ranging from 0.5 to 3 m in width and up to 100 m in length. The

194 dominant trends of the dykes strike E-NE and W-NW. Dykes were divided into two groups

195 based on their margins: 1) Ld$_1$ (Table 1) have poorly defined, glassy, pillowed, or peperitic

196 margins where they contact bodies of Lpi (Fig. 5C), and 2) Ld$_2$ (Table 1) have sharp, chilled, and

197 columnar jointed margins where they intrude all other lithofacies. Ld$_1$ is prevalent in the central

198 and high elevations of the edifice and is best exposed through extensional cracks. Ld$_2$ outcrop

199 sporadically ~~outcrop~~ in the central high elevations of CM ~~and are high in density~~, as well as,

200 along the eastern ~~margins~~margin of the edifice where they intrude subvertically ~~through the~~

201 stacked ~~walls~~piles of Lp.

202

5. Lithofacies associations

204 The ~~transitional eruptive history~~topmost portion of CM ~~involving explosive,~~

205 ~~effusive,~~edifice and ~~intrusive activity produced non-uniform deposition of all volcanic~~

206 ~~lithofacies. The deposits~~uppermost stratigraphic units are ~~not stratigraphically ordered in a~~

207 ~~planar fashion (i.e. a layer-cake model). Instead,~~heavily eroded which precludes us from

208 identifying the ~~buildup~~precise location and nature (e.g., fissure, cone, etc.) of the ~~volcano~~ vent.

209 However, we expect that the vent was ~~both lateral,~~near the present-day summit (elev. ~1580 m)

210 where ~~eruptive deposits spread out,~~within a 100 m radius, we find a multitude (~10) of cross-

211 cutting dykes intersecting the upper surface of the edifice. The volcano is volumetrically

212 dominated by subaqueous style lithofacies that result from and record an explosive onset to the

213 eruption followed by effusion (e.g., pillow lava) and intrusion (e.g., dykes). Furthermore, rather

214 than a simple layer-cake stratigraphy, the CM volcano grew: i) laterally where deposits source

215 from higher elevations ~~down~~and extend to the margins of the edifice, and ~~endogenous, through~~

216 ~~peperitic~~ii) endogenously by abundant intrusions ~~and dykes. The~~within the volcaniclastic pile.

217 Based on the detailed stratigraphic ~~relations are observed through the excellent crack exposures~~

218 ~~and allow us to determine~~relationships described above, we define four ~~dominant~~main lithofacies

219 associations (A-D) (Table 2).

220

222   Lithofacies association A comprises Lt_1, Lpi, and Ld_1 (Table 2). Lt_1 is intruded by Lpi

223 and Ld_1 at all elevations of the edifice, including exposures at the base of CM (Figs. 2B; 5). Ld_1

224 is observed to be in genetic relation to Lpi (Fig. 5C). Lt_1 outcrops at all elevations of CM, and

225 the deposits are pervasively palagonitized and lithified (Stroncik and Schmincke, 2002). The

226 mingling of Lpi within Lt_1 and examples of soft-sediment deformation indicate that Lt_1 was

227 saturated and unconsolidated at the time of intrusion. Additionally, the margins of Ld_1 are often

228 poorly defined and pillowed, further suggesting a saturated slurry-like host rather than a cooled

229 and lithified host at the time of intrusion. Lastly, Ld_1 is often seen tangential to 'blooming' Lpi,

230 suggesting that these two intrusive bodies are temporally related. Further petrographic

231 similarities (i.e. olivine and plagioclase phenocrysts) substantiate a co-genetic relationship

232 between Lpi and Ld_1. This lithofacies association reveals that unconsolidated ash and lapilli were

233 intruded by peperitic bodies, processes that require a water-saturated eruptive environment.

234 These stratigraphic relations imply an age succession of $Lt_1 > Lpi \geq Ld_1$.

235

237   Lithofacies association B comprises Lpi and Pi (Table 2); at CM peperite deposits (Pi)

238 are always spatially associated with masses of intrusive pillow lava (i.e. Lpi; Fig. 6). We

239 interpret these occurrences as fuel-coolant interactions (FCI) where the sudden contact of hot

240 magma (e.g., fuel) with cold, saturated sediment (e.g., coolant) generates a vapour film around

241 the intruding body (i.e. Lpi) (Doyle, 2000; Hooten and Ort, 2002; Martin and Németh, 2007).

242 Within the vapour films, instabilities may arise, causing local phreatomagmatic fragmentation

243 along the borders of the intrusion. Regions that experienced more stable vapour films result in

244 globular peperite texture (Fig. 6C) while areas with less film stability produce blocky peperite

245 textures (Figs. 6D) (Martin and Németh, 2007). ~~Most peperite deposits form along the margins~~

246 ~~of syn-volcanic intrusions and we take their widespread occurrence at or near the present-day~~

247 ~~surface of CM as an indicator of substantial post-eruptive erosion (e.g., Rosa et al., 2016).~~Most

248 peperite deposits form along the margins of syn-volcanic intrusions. The field relations for Lpi

249 and Pi show a contemporaneous origin, with both lithofacies forming as a result of intrusion into

250 wet, unconsolidated lapilli tuffs.

251

252 ~~5.3~~ Lithofacies ~~Association C~~

253 ~~This~~ association C comprises Tb, Ls, Lp, Lpi, and Lt (Table 2). The tuff breccia (Tb)

254 blankets the upper surface of CM and contains a large proportion (<50%) of sheet lava (Ls)

255 lithics, as well as moderate (30-40%) subrounded lithics of pillowed lava (Lp and Lpi), and

256 minor (>5%) subrounded blocks of Lt (Fig 7). The high volume of Ls lithics entrained within the

257 widespread tuff breccias is our best line of evidence that the sheet lavas preserved at higher

258 elevations were originally more extensive and volumetrically abundant. Post-eruptive erosion

259 (i.e. glacier erratics and scour marks; Fig. ~~The Tb matrix is comprised of~~8D) and collapse (i.e.

260 extensive network of extensional fissures) provide a reasonable explanation for the relatively

261 small remnant outcroppings of the Ls unit. The Tb matrix comprises moderately palagonitized,

262 explosively derived fine ash, quench fragmented ash and lapilli, and coherent lapilli lithics.

263 These findings suggest that Tb are syn-eruptive debris flows ~~comprised~~composed of previously

264 erupted volcanic lithics. The degree of palagonitization alteration throughout the unit

265 ~~indicates~~suggests subaqueous deposition ~~and may also have played a role in destabilizing the~~

266 ~~edifice slopes~~ (Schiffman et al., 2006). ~~The high volume of Ls lithics entrained within the~~

267 ~~widespread tuff breccias is our best line of evidence that sheet lavas made up a larger degree of~~

268 ~~edifice volume than what is preserved at the highly eroded present-day surface. Evidence of~~

269 ~~post~~The tuff breccias incorporate clasts derived from all other earlier stratigraphic units which,

270 combined with other stratigraphic relationships, suggests the succession ~~eruptive erosion (i.e.~~

271 ~~glacier erratics and scour marks; Fig. 8D) may explain why presently, Ls are only found as small~~

272 ~~remnant outcroppings. Given that the tuff breccias are comprised of earlier eruptive lithics (and~~

273 ~~not juveniles) this association suggests a temporal succession of~~ Lt>Lpi≥Lp>Ls>Tb.

274

275 ~~5.4~~ Lithofacies ~~Association~~association D

276 comprises Ld$_2$ ~~is associated~~ with all other CM lithofacies (Table 2). At CM, Ld$_2$ intrudes

277 through all other lithofacies with sharp, columnar jointed margins, including cross-cutting Ld$_1$ in

278 select locations. These contact relations indicate that Ld$_2$ is the latest preserved lithofacies from

10

279 the CM eruption. This last association suggests a temporal succession of

280 $Lt>Lpi=Pi\geq Ld_1\geq Lp>Ls\geq Tb>Ld_2$.

281

6. Chemistry and Petrography

283 6.1 Petrography

284   Detailed mineral abundances and componentry based on standard polarizing light and

285 scanning electron microscopy (Philips XL30) for all CM volcanic lithofacies are listed in Table

286 1. All coherent CM samples are olivine and plagioclase porphyritic, with glomeroporphyritic

287 clots visible in hand samples. A smaller population of samples also contains phenocrystic augite.

288 Petrographically, the pillowed dykes (Ld_1) have similar mineralogy as found in pillowed (Lpi)

289 and most sheet lavas (Ls). Jointed-dykes (Ld_2) commonly contain phenocrystic augite as do a

290 small proportion of pillow lava samples (Lp). Olivine phenocrysts are subhedral and unzoned.

291 Plagioclase phenocrysts are tabular and moderately zoned, with a very minor percentage (>5%)

292 showing sieve textures. When present, augite crystals are subhedral to anhedral.

293   Volcaniclastic samples are distinguished by sorting, grain size, structures, and

294 componentry. Lapilli tuffs (Lt_{1-3}) are ~~comprised~~composed of monolithic vitric juvenile fine ash

295 and coarse lapilli (Figs. 9B-H) and microlitic tachylyte juvenile pyroclasts (5-30%). Intact to

296 fragmented crystals of olivine and plagioclase are observed within the matrix of Lt_{1-3}. Juvenile

297 shapes range from blocky to highly vesicular (~60-70%) (Figs. 9B-H). Interstitial sediments are

298 observed between coherent Lp clasts but are notably different (i.e. coarse, jig-saw fit clasts

299 compared with Lt_{1-3} ~~()~~(e.g. Fig 9A).

300   Tuff breccia (Tb) componentry is highly variable. Tb is dominated by clasts of basalt

301 (Lpi, Ls, Lp) and contains minor blocks of Lt_1 within a matrix of vitric ash and lapilli. Tb matrix

302 is overall coarser than Lt_{1-3} although still contains abundant blocky and highly vesiculated

303 juveniles.

304

305 6.2 Geochemistry

306   Whole-rock major and trace element geochemical compositions were measured for 26

307 samples by X-ray fluorescence (XRF) analyses of fused discs and by inductively coupled

308 plasma-mass spectroscopy (ICP-MS), respectively. Samples span all CM volcanic lithofacies

309 (i.e. dykes, sheet and pillow lavas, and juvenile vitric-lapilli). Representative compositions of

11

310 whole rocks and glasses are reported in Table 3; analytical uncertainties are based on replicate

311 analyses done by Acme Analytical Labs Ltd., Vancouver, BC, Canada. A subset of samples was

312 analysed for FeO volumetrically by ALS Canada Ltd., North Vancouver, BC, Canada. Appendix

313 A contains the full data set and additional analytical details.

314   Figure 10A illustrates the chemical diversity of CM samples after Le Bas et. al, 1986

315 classification of volcanic rocks. All CM samples are subalkaline (Irvine and Baragar, 1971) but

316 display moderate spread in SiO_2 (~47-51 wt.%) and Na_2O-K_2O (~3-4 wt. %). The spread in

317 chemistry observed in Fig. 10A correlates with groups of samples having different phenocryst

318 contents. Samples that contain minor modal abundances of augite (in addition to olivine and

319 plagioclase) are typically higher in SiO_2 and Na_2O-K_2O wt. %. However, we find no significant

320 differences in mineralogy or chemical compositions that correlate with the stratigraphic position.

321   Fig 10B shows Mg#s (molar MgO/ (MgO +FeO*)∗100) of CM samples with relation to

322 SiO_2 wt.%. Within the Cascade arc, volcanic rocks having Mg# > 60 are considered "primitive"

323 indicating limited crustal influence (Green and Harry, 1999; Mullen and Weis, 2013). Our results

324 show CM samples range from Mg# ~55-67 with the majority of samples (~80%) between 60-66.

325 CM rare earth elements (REE) are normalized to a primitive mantle (Sun and

326 McDonough, 1989) and shown in Fig. 10C. All CM samples show similar anomalies (i.e.

327 positive Eu^{2+}, negative Y^{3+}). Little variations in trace element concentrations are observed

328 between samples, suggesting a similar mantle source for all CM eruptive deposits.

329   Cracked Mountain rare earth elements (REE) shown in Fig. 10C normalized to chondrite

330 composition after Sun and McDonough (1989). There is little variation in trace element

331 concentrations between samples, including similar anomalies (i.e. positive Eu^{2+}), suggesting a

332 similar mantle source for all CM deposits.

333

7. Geochronometry

335 7.1 Radiogenic ^{40}Ar /^{39}Ar Results

336   Two CM samples (MH-19-055, 031) were selected for ^{40}Ar /^{39}Ar radiometric dating at

337 the WiscAr Geochronology Labs, University of Wisconsin-Madison, USA. The holocrystalline

338 dyke sample (MH-19-031) proved to be non-measurable because of excess argon trapped in the

339 plagioclase minerals. This is a common issue with basaltic dykes (of young ages) (Brian Jicha,

340 pers. comm. 2021) and with subglacially erupted deposits of all compositions (Clay et al., 2015).

341 The second CM sample (MH-19-055) was collected from the radially jointed interior of a pillow

342 lava outcrop. This sample contained low radiogenic argon but the analysis was still possible

343 through twenty-four heating steps with moderate uncertainty. The results yielded a plateau age of

344 401.6 ± 38.1 ka for crystallization of the groundmass (Fig. B1). Errors are quoted at a 2σ (95%

345 confidence) level and are propagated from all sources except for mass spectrometer sensitivity

346 and the age of the flux monitor. Appendix B contains analytical procedures used and table B1

347 contains complete measured data for heating steps.

348

349 7.2 Paleomagnetic Methods and Results

350 A total of nine sites across the CM edifice were selected for ~~sampling at CM, with the~~

351 ~~objectives of gaining representative data from approximately~~ the paleomagnetic study. The sites

352 were chosen to span the entire stratigraphic sequence (i.e. oldest to youngest ~~CM lithofacies. One~~

353 ~~sample)~~ and one site (Site 2) was replicated ~~to test~~ for field and lab reproducibility. ~~All samples~~

354 ~~were drilled into volcanic lithofacies~~ (Table C1). We preferentially sampled units that cooled

355 quickly, thus locking in the geomagnetic field orientation at the time of emplacement (e.g.,

356 Johnson et al., 2008). Efforts were made to sample ~~in situ~~only intact outcrops ~~and avoid~~thereby

357 avoiding areas suspected of ~~obvious~~ post-emplacement ~~rotation. Standard~~movement.

358 Approximately eight standard 2.5-cm-diameter paleomagnetic cores were ~~drilled in the field.~~

359 ~~Approximately eight cores were taken from most sites~~collected from each site and a minimum of

360 three cores from each outcrop. Each sample was oriented using a magnetic compass, and where

361 possible a sun compass was used in conjunction with magnetic orientations.

362 CM samples were analyzed at the paleomagnetic laboratory at the University of

363 Lethbridge, Alberta. Magnetic susceptibility was determined with a Sapphire Instruments (SI-

364 2B) susceptibility meter. The magnetization of each sample was measured with an AGICO JR-

365 6A spinner magnetometer before demagnetization and again after each level of stepwise

366 demagnetization. CM samples were held in magnetic shields following field collection and

367 between laboratory measurements. All samples were subjected to alternating field (AF)

368 demagnetization, performed using an ASC Scientific D-2000 demagnetizer with a three-axis

369 manual tumbler, and carried out at 10 milli-tesla (mT) steps (up to 200 mT). Thermal

370 demagnetization was carried out at 100, 200, 300, 400, 500, 525, 550, and 580 °C, using an ASC

371 Model TD48 dual-chamber thermal demagnetizer to confirm that alternating field

13

372 demagnetization was sufficient to resolve the primary remanence. Directions of characteristic

373 magnetization were determined for each sample by principal component analysis (Kirschvink,

374 1980) using Remasoft version 3.0 (Chadima and Hrouda, 2006). Mean directions of

375 characteristic magnetization were calculated for each site and an overall mean was also

376 calculated (Appendix C; Table C1). All samples were subject to stepwise AF demagnetization

377 and principal component analysis and mean directions were calculated from the AF data only.

378 All paleomagnetic samples are normally magnetized (Fig. 11A; Table C1). The ~~site~~ mean

379 directions of sites are consistent for eight of nine sites, where all eight sites plot within the

380 uncertainty circle (α_{95}) about the overall mean (N=8) with a declination of ~~346.54~~347.3 ˚ and

381 inclination of 76.~~5~~46 ˚, and Fisher precision factor of $k = 351$, $\alpha_{95} = $ ~~2.99~~3.0° (Fig. ~~12A~~11A).

382 Typical, well-behaved demagnetization characteristics are shown for samples from Lt$_1$ and Ld$_1$

383 respectively in Figs 11B and C.

384 All paleomagnetic samples produced stable directions of magnetization following

385 stepwise demagnetization. Alternating field demagnetization, applied to all specimens, exhibited

386 linear decay to the origin on orthogonal projections (Fig. ~~11A~~11B and ~~B~~C). The median

387 destructive fields range from 20–80 mT and final directions are often stable up to 200 mT

388 alternating field demagnetization (see ~~CMV060A~~CMV015A, Fig. 11B) indicative of single-

389 domain magnetite. Thermal demagnetization showed complete demagnetization at 550 to 580

390 °C, typical of fine-grained (single domain) magnetite as the magnetic carrier (see CMV029, Fig.

391 11C). Note that single-domain magnetite is the optimal magnetic mineral and grain size for

392 producing reliable paleomagnetic directions. The magnetic susceptibility values of CM volcanics

393 range from 0.4-1.0 x 10-3 SI (median value of 0.5 x 10-3 SI) for the flows composed of

394 pyroclastic density currents and 2.4-16.4 x 10-3 SI (median value of 4.5 x10-3 SI) for dykes.

395 Mean natural remanent magnetization for CM volcanics is 9.4 A/m (range 0.4–22.0 A/m). ~~These~~

396 ~~findings indicate that the bulk of the sampled lithofacies at CM have the same emplacement age~~

397 ~~(i.e. monogenetic).~~

398 ~~One site (Site 1; Table C1) provided seven samples that were outliers compared to the~~

399 ~~results obtained from the eight other sites (2-9). The sampling location for Site 1 was from basal~~

400 ~~lava (Lp) exposed below the SE cliff margin of the edifice. Of the seven cores analyzed from~~

401 ~~Site 1, we accept three as likely due to edifice rotation not evident in the field at the time of~~

402 ~~sampling. These three samples gave coherent results with a mean declination and inclination of~~

403 ~~34.37˚ and 72.88˚ respectively. From our observed crack orientations (e.g. Fig. C1) we believe~~

404 ~~the edifice is collapsing in the downslope directions. This suggests that Site 1 may have~~

405 ~~experienced east (southeast) trending rotation. Based on a comparison of the stereographic~~

406 ~~orientation of Site 1 mean data (from three coherent samples) with the whole CM mean data, we~~

407 ~~find that a rotation of ~12˚E is observed (Fig. C1), which is consistent with our interpretation of~~

408 ~~extensional collapse. Additionally, we calculated the approximate crack width from the ~12˚ of~~

409 ~~interpreted rotation and thickness of block (e.g. deposit thickness above basement) to be ~20 m.~~

410 ~~Again, this calculated crack width is consistent with observed crack widths seen along the outer~~

411 ~~margins of CM, and further supports our interpretation of Site 1 paleomagnetic data. The~~

412 ~~remaining four samples collected from Site 1 returned highly dispersed results that were~~

413 ~~inconsistent with both the mean CM magnetic data of Sites 2-9 and the three Site 1 samples that~~

414 ~~plot within our plausible edifice collapse direction. We interpret the remaining four samples to~~

415 ~~be a result of the reorientation of blocks (i.e. not in-situ to edifice lava wall) not obvious at the~~

416 ~~outcrop at the time of sampling.~~

417 The common pole direction obtained for all volcanic units, including the latest dykes,

418 implies a common eruption age indicating a monogenetic origin for the volcano. Furthermore,

419 the data from each site showed no indication of rotation or tilt as the mean direction is within the

420 expected paleosecular variation (see mean of sites 2-9 and GAD inclination for sampling

421 latitude, Fig. 11A, and Table C1). The sole exception was Site 1 (Table C1) where the seven

422 cores record a different mean pole direction compared to the other eight sites (2-9). Site 1 is a

423 lower elevation cliff-side exposure of pillow lava (Lp) on the SE margin of the edifice. Of the

424 seven cores, three can be ascribed to post-emplacement rotation and yield coherent results with a

425 mean declination and inclination of 34.4˚ and 72.9 respectively. The rotation is likely due to

426 partial extensional collapse and, relative to the mean pole direction for the CM edifice, we

427 calculate a downslope rotation of ~12˚E (Fig. C1). This rotation has a calculated maximum

428 crack width of ~20 m which accords well with the observed fissures found on the outer margins

429 of CM (e.g., Fig. 3B).

430

431 **8. Discussion**

432 ~~8.1 A glaciovolcanic eruption within an englacial lake~~

15

433 ——— Our mapping and analysis suggest CM is a monogenetic edifice with no evidence of time

434 lapses during the eruption. The results of paleomagnetic analyses concur with our field

435 observations that the varying lithofacies were emplaced in one paleomagnetic moment (< 1,000

436 years; Turner, 1987; Barletta et al., 2010; Lisé-Pronovost et al., 2013) at 401 ±38 ka based on our

437 best $^{40}Ar/^{39}Ar$ age determination. CM lithofacies (i.e. pillow lavas, palagonitized tuffs, and

438 peperites) indicate a subaqueous eruptive paleoenvironment, however, the edifice is situated in

439 an alpine setting with extremely steep-sided valleys on all sides (Fig. 3). There are no reasonable

440 physical barriers (i.e. mountains or ridges) to provide a paleo-closed catchment to form an alpine

441 lake, thus, we ascribe a glaciovolcanic origin. CM lacks the lithofacies succession in a "Classic"

442 mafic tuya model (e.g., pillow effusion, hyaloclastites, lava-fed deltas, and capping lava)

443 (Smellie, 2007; Jakobsson and Gudmundsson, 2008; Edwards et al., 2015). The Russell et al.,

444 (2014) descriptive classification would describe CM as a transitional, tephra-dominated, tuya.

445 ——— The CM volcanic succession is ~250 m thick and subaqueous lithofacies outcrop at

446 elevations as high as ~1,650 m a.s.l where they have relief of ~800 m above the major drainages.

447 At the highest elevations of CM (~1,600-1650m a.s.l), we find small remnant subaerial sheet

448 lavas (Ls) but no evidence of preserved 'passage zones' (i.e. surfaces that mark transitions

449 between subaqueous and subaerial depositional environments during volcanic eruptions) (Jones,

450 1970; Smellie, 2006; Russell et al., 2013; Edwards et al., 2015). This provides strong evidence

451 that the englacial meltwater lake was sustained throughout the majority of the eruption and the

452 lake surface elevation continued to rise with the growth of the edifice. The absence of lava-fed

453 delta sequences containing pillow breccias at Cracked Mountain (i.e. aggradation of

454 volcaniclastic material from lava flowing into the water; Edwards et al., 2015) suggests Ls

455 formed as overlapping effusions of subaerial lava (e.g., Skilling, 2009; Russell et al., 2013)

456 where the englacial lake had partially drained at a later time in the edifice buildup.

457 ——— The present-day Ls outcrops are small; however, we find substantial Ls lithics entrained

458 in the thick, massive Tb that cover much of the CM surface. These findings suggest a significant

459 volume of subaerial lava erupted during the late-stage edifice formation. Two scenarios would

460 give rise to the subaerial capping lavas: 1) The edifice grew above the paleolake level, becoming

461 emergent, where a passage zone would denote the maximum lake level, or 2) the water level

462 dropped (via drainage) giving rise to dry, subaerial eruptive environment. In the latter case, the

463 subaerial lavas would mark the minimum height that lake level reached (i.e., overlap) (Russell et

464 al., 2013). We favour the second scenario of overlap lavas because we find no definitive passage

465 zones that would suggest subaerial lavas aggraded into water (i.e. lava-fed-deltas) and our

466 models of meltwater produced versus paleolake capacity suggest a moderately 'leaky' lake

467 system must have been present in the later stages of the eruption (see section 8.4). Thus, the

468 elevation of Ls (~1,650 m) marks the minimum level for the paleo-englacial lake.

469

470 8.28.1 Explosive Onset to Glaciovolcanic Eruption

471   The lapilli tuff deposits (e.g. Fig 9B-H) are comprised ofcomprise coarse to fine ash

472 (>100 μm) particles that are commonly highly vesiculated (<60%). The abundance of fine ash in

473 CM Lt deposits suggests explosive magmatic and/or phreatomagmatic fragmentation

474 (Zimanowski et al., 1991; White and Valentine, 2016; Latutrie and Ross, 2020). CMThe Lt

475 deposits comprise both blocky ash (e.g. Fig 9B) and micro-vesiculated cuspate ash (e.g. Fig 9D

476 and F) suggesting that both phreatomagmatic (external water) and magmatic (internal volatiles)

477 drove the explosive fragmentation processes. We note that blocky juveniles are dominant in Lt_{1-3}

478 suggesting that phreatomagmatic reactions involving glacial meltwater played the largest role in

479 the explosive eruptive style.

480   Based on the overall bedform and textures found in Lt deposits, we assert that the

481 depositional environment was wet and probably (shallow) subaqueous. The massive, character

482 and moderate to poor sorting of Lt_1 suggest an influx of fragmental material erupted

483 throughcontinuous deposition from a sustained column, rather than periodic explosive pulses

484 which would generate moderately sorted and bedded deposits via elutriation (e.g., White, 1996,

485 2000) and the. The lack of welding between matrix and juvenile material suggests, compaction,

486 or clast imbrication is also consistent with a water-rich intergranular phase (rather than gas) was

487 present throughfor these eruption-fed aqueouspyroclastic density currents (White, 2000; Brand

488 and Clarke, 2009).

489   The thinly bedded, moderate to well sorted, and weakly normally graded Lt_2 is indicative

490 of deposition from dilute pyroclastic density currents (i.e. pyroclastic surge; Fisher and Waters,

491 1970; Brand and Clarke, 2009). These deposits reflect phreatomagmatic explosive pulses that

492 dispersed highly fragmented ash laterally and elutriated through the water column. The shallow

493 dipping cross-bedding preserved in some Lt_2 outcrops (Fig. 4B) is consistent with subaqueous

494 pyroclastic deposits (Moorhouse and White, 2016). The overall lack of well-sorted beds of fine

495 ash, characteristic of thick water column elutriation, makes a shallow subaqueous setting most

496 plausible.

497 ~~Lt₃ is composed~~Lt$_3$ contains moderate volumes (20-40 %) of non-welded spatter within

498 moderately to well-sorted ash and lapilli matrix (Fig. 4C). We propose that the Lt$_3$ deposits

499 record periods of increased magma flux, volatility, and/or a decreased water supply (at the vent),

500 where a strombolian style burst ejected largely vesiculated and fluidal clasts (Latutrie and Ross,

501 2020). We find that the overall characteristics of the Lt$_3$ deposits indicate a shallow aqueous to

502 emergent depositional environment. This assertion is based on a lack of bomb sags within these

503 deposits and chilled but not quenched (or pillowed) spatter clasts. The two outcrops of Lt$_3$ are

504 located at upper elevations of CM, and not observed within lower to middle stratigraphy. Our

505 interpretation is Lt$_3$ represents localized magmatic generated fallout mixed with

506 phreatomagmatically generated pyroclastic density currents in shallow aqueous to locally drained

507 regions of CM.

508 Explosively derived Lt deposits are present at all elevations of CM (Fig. 2) and ~~we~~

509 ~~estimate that it comprises~~comprise ~30% of the entire edifice ~~by volume~~ (Table 1~~).~~), and

510 excluding intrusions, are closer to 60% of the volcano volume. Our findings indicate that not

511 only was the onset of the CM eruptions explosive but that explosivity was sustained ~~through the~~

512 ~~middle to late stages~~throughout most of the eruption. This explosive-styled eruption makes CM

513 unique within the GVB, being only one of five other identified tephra-dominated glaciovolcanic

514 landforms (Wilson and Russell, 2018). We ~~hypothesise~~speculate that ~~these~~ explosive ~~styled~~

515 onsets to glaciovolcanic eruptions may ~~not~~ be ~~uncommon in any glaciovolcanic setting but~~

516 ~~rather~~significantly more common than recognized and underestimated because tephra-dominated

517 landforms are ~~less likely to be preserved, compared~~highly susceptible to ~~lava-dominated tuyas, if~~

518 ~~multiple cycles of glaciation occur after edifice formation~~erosion. We suggest CM's transitional

519 eruptive history, which produced intrusive and effusive coherent lavas, helped create a stronger

520 structure more resistant to glacial erosion.

521

522 ~~8.3 Model for CM eruption~~

523 ~~The glaciovolcanic deposits record a complex sequence of events indicative of a~~

524 ~~primarily subaqueous setting. We find that the interior of the edifice is dominated by tephra and~~

525 ~~peperitic intrusions, while the margins are comprised of coherent lavas and lava-dominated~~

18

526 ~~breccias. These variable lithofacies speak to transitions in eruptive style from explosive to~~

527 ~~effusive. Lastly, the shape and present-day partial collapse of CM (in the form of cracks) provide~~

528 ~~a post-eruptive context for the paleoenvironmental setting of the eruption. Our model for the CM~~

529 ~~sequence of events (Fig. 12) is described below.~~

530 The investigation of Cracked Mountain deposits records a complex sequence of events

531 beyond the initially explosive onset. Our analysis suggests the following conceptual model for

532 the evolution of the CM eruption (Fig. 12):

533 1. An explosive, Surtseyan phase dominated the initial CM eruption, producing a subaqueous

534 tephra cone ~~comprised of~~comprising Lt_1 (Fig. 12A). ~~This~~ Our interpretation of this initial

535 phase is ~~evidenced by the predominant bedform structure and componentry of Lt_1 (i.e.~~

536 ~~massive, moderately sorted vitric ash and lapilli) which we interpret to be derived from a~~

537 ~~sustained phreatomagmatic column and proximal high-density pyroclastic flows. Our~~

538 ~~temporal assessment for this phase is based on stratigraphic relations~~ detailed above.

539 1. ~~(i.e. Association A; Fig. 5) between Lt_1 and Lpi. This association is seen from the base of the~~

540 ~~edifice (e.g. Fig 2B) through to the summit and is supported by the fact that we find no~~

541 ~~exposure where CM volcanics post-date Lt_1, making it the oldest mapped unit.~~

542 2. ~~The second CM eruptive phase is characterized by the~~ transition from explosive to effusive

543 (and intrusive) activity (Fig. 12B~~. Peperitic~~) is expressed by peperitic dykes (Ld_1) and

544 bodies (Lpi~~)~~). These intrusions inflate the edifice ~~from within,~~endogenously and dykes that

545 ~~reach~~pierce the margins of the tephra pile form stacks of pillow lavas (Lp) ~~that pile up on~~ at

546 the margins of the volcano. ~~The presence of peperites (Pi) along the margins of Lpi (Fig. 6)~~

547 ~~indicates that these large lava bodies were intrusive rather than extrusive. This relationship~~

548 ~~shows that phase 2 occurred rapidly after phase 1, where the previously erupted tephra was~~

549 ~~still unlithified.~~

550 3. ~~The third CM eruptive phase involved continued intrusions and effusions through the earlier~~

551 ~~erupted lithofacies, forming effusive lavas (Ls), breccias (Tb), and dykes (Ld_2) (Fig. 12C).~~

552 ~~The columnar jointing of the remnant Ls outcrops suggests the lake level was draining~~

553 ~~periodically at this point, likely through well-established drainage channels that prevented~~

554 ~~lake volumes from reaching amounts capable of floating the encapsulating glacier (see~~

555 ~~section 8.4 below). The massive tuff breccias contain lithics from all other volcanic~~

556 ~~lithofacies, including rounded, block-sized Lt_1. This relationship suggests explosivity~~

557 ~~persisted throughout the later stages of the CM eruption, where underlying Lt₁ was ripped up,~~

558 ~~subrounded, entrained, and deposited in Tb. The later stage explosivity is further~~

559 ~~substantiated by our findings of high stratigraphy fire-fountaining deposits (Lt₃) that show~~

560 ~~signs of 'dryer' deposition in locally drained regions of the edifice.~~Late-stage intrusions and

561 effusions produce effusive lavas (Ls) and dykes (Ld₂) and associated breccias (Tb), (Fig.

562 12C). The culmination of the CM eruption is marked by late-stage dyke activity (Ld₂) that

563 cut through all other lithofacies. ~~Despite changes in eruptive styles (i.e. explosive and~~

564 ~~effusive) and environments (i.e. wet and dry), the~~The paleomagnetic signatures of all CM

565 deposits overlap within one paleomagnetic moment. Thus, the CM eruption taking place

566 from stages 1-3 can be thought of as more or less continuous.

567 The final stage (4) in the CM formation was non-eruptive and characterized by glacial erosion

568 and edifice collapse (Fig. 12D). The timing of glacial retreat ~~after the CM eruption~~ is unclear, but

569 ~~we do find evidence of glaciation (i.e.~~ the present-day surface features bedrock erratics and scour

570 ~~marks) on the present-day surface. These findings show that at some point post-eruption, CM~~

571 ~~was once again enveloped in an ice sheet. We propose that this~~ indicating post-eruptive

572 glaciation ~~removed portions of the upper CM eruptive stratigraphy.~~ The widespread distribution

573 of large extensional fissures and ~~carved the over-steepened edifice margins that we presently see~~

574 ~~today. The final process we model at CM is the formation of the~~ cracks ~~after the glacial~~

575 ~~unconfinement. We attribute this partial edifice collapse to the removal of confining pressure~~

576 ~~after the ice sheet retreated. The lack of glacial deposits~~results from the retreat of the enclosing

577 ice sheet which originally buttressed the steep-walled edifice. Glacial erratics are not found

578 within ~~the cracks indicates that they formed after the localized last glacial maximum and are~~

579 ~~probably continuing to collapse to the present day.~~these fissures which may suggest that the

580 edifice was mainly enclosed (and buttressed) by regional and local ice until the Last Glacial

581 Period (i.e. <115 -120 ka).

582

583

584 8.~~4~~2 Paleoenvironmental ~~reconstruction~~ implications

585 ~~We find englacial erupted~~   Our mapping and analysis suggest CM is a monogenetic edifice

586 with no evidence for significant time gaps during the eruption. The results of paleomagnetic

587 analyses concur with our field observations that the varying lithofacies ~~at elevations up to~~were

588 emplaced in one paleomagnetic moment ($\lesssim$

589 1,000 years; Turner, 1987; Barletta et al., 2010; Lisé-Pronovost et al., 2013) at 401 ± 38 ka

590 (Fig. B1).

591   The CM lithofacies (i.e. pillow lavas, palagonitized tuffs, and peperites) indicate a

592 subaqueous eruptive paleoenvironment, however, the edifice is situated at a high elevation in a

593 high relief environment and surrounded by steep-sided deep (~800 m) valleys (Fig. 3). ~~650 m~~

594 ~~a.s.l, with the volcanic succession built ~250 m atop the basement rocks. These findings~~

595 ~~require~~We suggest a glaciovolcanic eruption into a sustained englacial lake of meltwater

596 enclosed by a substantial ice sheet on the basis that there are no obvious physical barriers (i.e.

597 mountains or ridges) to allow for a conventional paleo-lake. The volcanic lithofacies suggest that

598 the englacial lake was sustained throughout the eruption and that the lake surface elevation

599 continued to rise with the growth of the edifice. The CM volcano is best described as a

600 transitional, tephra-dominated, tuya after the descriptive classification of Russell et al., (2014)

601 and its lithofacies associations make it distinct from the classical mafic tuya model (e.g., pillow

602 effusion, hyaloclastites, lava-fed deltas, and capping lava) (Smellie, 2007; Jakobsson and

603 Gudmundsson, 2008; Edwards et al., 2015).~~which CM erupted into~~

604   The CM volcanic succession is ~250 m thick and rests on basement rocks at ~1,250 m

605 a.s.l (Fig. 2A). Subaqueous lithofacies outcrop at elevations as high as ~1,650 m a.s.l where they

606 have relief of ~800 m above the major drainages. At the highest elevations of CM (~1,600-1650

607 m a.s.l), we find small remnant subaerial sheet lavas (Ls) although the abundance of Ls lithics

608 within the thick succession of Tb deposits may suggest that there was much more subaerial lava

609 originally. There are, at least, two scenarios that would ~~have been ~250 m deep along the edifice~~

610 ~~margins~~explain subaerial capping lavas within the englacial lake environment. The most likely

611 scenarios are that, either, i) the edifice grew and became emergent above the paleolake level to

612 form a classic passage zone defining a maximum lake level (Jones, 1970; Smellie, 2006; Russell

613 et al., 2013; Edwards et al., 2015) or ii) the level of the englacial lake decreased due to subglacial

614 drainage creating a "dry" subaerial environment. In the latter case, post-draining subaerial lavas

615 overlapping the subaqueous lithofacies establish a minimum level of the englacial lake (Smellie,

616 2006; Skilling, 2009; Russell et al., 2013).

617   There is no direct evidence for a passage zone relationship (i.e. beds of pillow lava

618   breccias or lava fed deltas) so we favour the second scenario involving overlap lavas wherein the

619   elevation of Ls at ~1,650 m defines a minimum level and, thus, a minimum depth of ~250 m for

620   the paleo-englacial lake (Fig 13B). We ~~use these findings to investigate the minimum~~have used

621   the shape and size of the CM edifice and the surrounding topography to constrain the maximum

622   dimensions and volume of the paleo-englacial lake. The paleo-topography beneath the CM

623   edifice (Figs. 3, 13A) limits the size of the syn-eruptive englacial lake. Relative to the present-

624   day edifice we estimate the lake may have extended <100 m to the south and <300 m to the east

625   but been limited to < 50 m to the north and west by very steep drainages. Assuming an

626   asymmetric shape of 1,800 m long and 1,300 m wide and a maximum depth of 250 m (Fig. 13B)

627   yields a maximum lake volume at ~0.36 km^3. The present-day (i.e. minimum) volume of the CM

628   volcano is ~0.18 km^3 such that the lake could only store < 0.18 km^3 of water (i.e. maximum lake

629   volume – edifice volume). This strongly suggests that throughout the eruption the englacial lake

630   was never fully sealed but was a leaky system where meltwater production and sub-ice drainage

631   were nearly matched (cf. Russell et al. 2014). As the eruption waned, melting of the enclosing

632   ice became less efficient and drainage became dominant, leading to a lowering of the lake level

633   to allow for subaerial eruption of lavas (Fig. 12C).

634   To sustain a lake level of 250 m requires a rate of leakage less than the rate of meltwater

635   accumulation and also requires an ice thickness ~~at the time of the CM eruption. In glacial lakes,~~

636   ~~when the water level exceeds ~90% of ice thickness,~~above ~280-300 m to counterbalance the

637   hydrostatic ~~pressures exceed glaciostatic pressures, causing the ice to float~~lake pressure (e.g.,

638   Tweed and Russell, 1999; Smellie, 2006; Edwards et al., 2015). The surrounding topography

639   features steep drainages with valley floors at ~ 800 m a.s.l. (i.e. ~~In the case of CM, we find that~~

640   ~~to sustain a lake level of 250 m without resulting in hydrostatic drainage, the ice must have been~~

641   ~~at least ~280 m above the basement rocks. We find no field-based evidence of rapid subaerial~~

642   ~~edifice growth that would indicate a deluge of meltwater occurred (i.e. jökulhlaups; Tweed and~~

643   ~~Russell, 1999; Gudmundsson et al., 2004; Russell et al., 2013). Therefore, the minimum ice~~

644   ~~cover must have reached 1,680 m a.s.l. Given that CM is not located beneath peaks that could~~

645   ~~have sourced an alpine glacier, the encompassing ice must have been a continental ice sheet~~

646   ~~(CIS). We use the models of CIS growth and decay (e.g.,~~Meager Creek and Elaho valley; Figs. 3

647   and 13). This suggests that the enclosing ice sheet, an earlier (paleo-) incarnation of the

648 Cordilleran Ice Sheet (CIS) at 401 ± 38 ka, was at least 880 m thick. This minimum ice thickness

649 has implications for the distribution of the paleo-CIS and suggests that most of the surrounding

650 landscape was under ice except at the highest elevations (Fig. 13A and C; Clague, 2009; Wilson

651 et al., 2020) to show that the surrounding Meager Creek and Elaho Valley's would have been

652 filled with ice, and only the upper elevation peaks of the Mount Meager massif would be

653 emergent (Fig. 13A). We use the constraints of the surrounding topography to calculate the

654 minimum thickness of the CIS. The lowest point in the northward Meager Creek valley is ~800

655 m a.s.l, thus the CIS was > 880 m thick (given the elevation of ice above CM at 1,680 m a.s.l)

656 (Fig. 13C)..

657   We use the shape and size of CM and the surrounding topography to approximate the

658 maximum dimensions and volume of a paleo-englacial lake. Based on the gradient of underlying

659 basement rocks (Fig. 3), we estimate that the englacial lake is unlikely to have extended more

660 than 50 m past the north and west CM borders, ~100 m from the south edge, and up to 300 m at

661 the east edifice corner (Fig. 13A). We estimate that the lake had an asymmetric shape, 1800 m

662 long and 1300 m wide, and a maximum depth of 250 m (Fig. 13B). From our estimated

663 dimensions, and assumed uniform lake depth, we calculate maximum lake volume at ~0.36 km^3.

664 We estimate the volume of erupted material to be ~0.18 km^3 based on present-day edifice

665 dimensions and thickness. Throughout the eruption, water volume (within the lake) would have

666 been displaced by erupting material, and by stage three (i.e. edifice maximum volume), only

667 ~0.18 km^3 (i.e. max lake volume – edifice volume) of water could have been stored in the lake.

668 The heat capacity of a basaltic eruption the size of CM is capable of melting more than 2 km^3 of

669 water from surrounding ice (e.g., Gudmundsson et al., 2004; Kelman, 2005; Tuffen, 2007). This

670 volume of meltwater exceeds the capacity of our proposed maximum paleolake and negates the

671 possibility of a fully sealed lake catchment system. Instead, we propose a leaky lake system, with

672 established drainage channels (Fig 13).

673   The CM age of 401 ± 38 ka fits withincoincides with the waning of marine δ^{18}O isotope

674 stage (MIS) 12 glacial period (~470-425 ka) intoand the warming period of MIS 11 (~420-375

675 ka) (Lisiecki and Raymo, 2005) (Fig. 14). The shift in global δ^{18}O during associated with the

676 MIS 12 to 11 transition is the most drasticlargest of all the Pleistocene cycles (e.g. Fig 14),

677 signifyingand signifies rapid global warming. Thus, we believe a CIS (e.g. Fig 14; Lisiecki and

678 Raymo, 2005). The ~850 m (or thicker) thickness of ~850 m at 400 ka (i.e. middlethe paleo-CIS

23

679 enclosing the Cracked Mountain volcano is inconsistent with the mid-point of MIS 11) was

680 unlikely. Instead, we favour at 400 ka. However, if we accept a slightly older $^{40}Ar/^{39}Ar$ age of

681 ~425 ka for the Cracked Mountain eruption. This slightly older age fits(still within the analytical

682 uncertainty of the $^{40}Ar/^{39}Ar$ results and places) (Table B1) for the eruption more within the

683 waning ofof Cracked Mountain, the age accords well with the global ice period (MIS 12)

684 (Lisiecki and Raymo, 2005; Batchelor et al., 2019). Eruption ages for other volcanoes in the

685 GVB are sparse, however, Wilson and Russell (2018) report glaciovolcanic eruptions during

686 MIS 12 within the Mount Cayley volcanic field (Ember Ridge, unpublished age), as well as,

687 subaerial lavas erupting in the Salal glacier field during MIS 11 (Nichols Valley at 405 ka).

688 These additional age constraints, although limited, do support the eruption of Cracked Mountain

689 into an early (late-Pleistocene) incarnation of the CIS within SW British Columbia at ~ 425 ka.

690 -We also speculate that at this time, there may have been a large-scale decompression

691 effect on the Earth's crust driven by rapid deglaciation at the end of MIS 12. The link between

692 volcanism and crustal unloading during periods of deglaciation has been modeled throughout the

693 GVB (e.g., Wilson and Russell, 2020) and explored in Icelandic and Andean glaciovolcanic

694 fields (e.g., Carrivick et al., 2009; Guillot and Ponce, 2021). We, therefore, find it entirely

695 feasible that the CIS retreat in SW British Columbia would have triggered magmatic ascent

696 through the unloaded crust, leading to the CM eruption.eruption of the Cracked Mountain

697 volcano (as well as others). Lastly, since records of older glaciation cycles tend to be obscured

698 by younger waxing and waning of ice sheets, our findings at CM provide useful temporal and

699 physical constraints for the CIS extent in SW British Columbia during the mid-Pleistocene.

700

9. Summary

701

702 The Garibaldi Volcanic Belt contains many Quaternary glaciovolcanic centres. The study of

703 these volcanoes provides paleoclimatic evidence at the time of the eruptions and contributes to

704 the understanding of magma, ice, and water interactions more generally. Here, we present the

705 first physical volcanological study of Cracked Mountain, a transitional, tephra-dominated tuya.

706 Our findings indicate an initially explosive eruption that later transitioned into a mixture of

707 intrusive and extrusive styleseffusive activity. We characterize the explosivity as dominantly

708 phreatomagmatic, manifested as Surtseyan style eruption in a shallow englacial lake. Peperitic

709 intrusions and pillow lava effusions are the largest coherent units by volume, indicating that

710 subaqueous conditions persisted through the middle and later stages of the eruption. Small

711 remnants of subaerially erupted lavas are preserved at the highest elevations, suggesting that the

712 lake drained periodically in the later stages of the eruption. This claim is supported by our

713 modeling of paleolake dimensions and volumetric capacities. Lastly, our temporal investigation

714 of the eruption concludes that CM was monogenetic, erupting ~425 ka between MIS 11 and 12.

715 We model the localized, mid-Pleistocene CIS as having a minimum thickness of ~850 m,

716 reaching elevations of 1,680 m a.s.l or higher.

Figure Captions

Figure 1: Location and geologic setting of Cracked Mountain volcano. A) Map of the Cascade
volcanic arc in the USA and Canada (i.e. Garibaldi volcanic belt (GVB)) (modified from Mullen
and Weis, 2013; Wilson and Russell, 2017). B) Undivided geological map of MMVC
distribution of Mt. Meager volcanic deposits (MV), basement (Bu) throughout the region
(Woodsworth, 1977; Read, 1979; Harris and Russell, 2021). The youngest MMVC eruption,
2350 B.P. Pebble Creek Formation (PcF) (Hickson et al., 1999; Stewart et al., 2008) is
differentiated from other MMVC volcanics. Cracked Mountain (CM) is situated south of the

929 main MMVC (Wilson and Russell, 2018; Harris and Russell, 2021). Map projection based on
930 Universal Transverse Mercator, Zone 10U North American Datum 1983.
931

932 **Figure 2:** Geology of Cracked Mountain. A) Geologic map showing the distribution of CM
933 volcanic lithofacies. Dyke location and orientations are shown in red; extensional cracks are
934 shown in black. The volcanic edifice unconformably overlies basement granodiorites (Bg) and
935 mica-schists (Bs). ~~Black~~White-numbered dots show locations of representative stratigraphic logs
936 (B, C). B) Graphic logs showing volcanic stratigraphy at various locations and elevations ~~(black~~
937 ~~numbered dot)~~ within the map area (depicted in Figs. 2A). Lithologies are depicted with various
938 patterns and symbols while corresponding map units are shown in the same colours as Fig. 2A.
939 Red lines shown in map units represent intruding dykes observed within the lithologies of the
940 graphic logs. Map projection based on Universal Transverse Mercator, Zone 10U North
941 American Datum 1983.
942

943 **Figure 3:** Physiographic setting of Cracked Mountain volcano. A) NE-SW oriented Google
944 Earth imagery of Cracked Mountain showing the location of volcanic deposits overlying
945 basement rocks (white-arrows). ~~Visible~~B) N-S oriented Google Earth imagery of Cracked
946 Mountain (outlined in white), highlighting visible cracks parallel the steep drainages. ~~B~~C) South-
947 West facing DEM hillshade map showing CM volcanics (red shaded outline) situated above
948 present-day Meager Creek and Elaho Valleys.
949

950 **Figure 4:** Field photos displaying bedform structures of CM lapilli tuffs: A) Field photo showing
951 ~2 m thick exposure of massive, moderately sorted ash and lapilli tuff underlying poorly sorted
952 tuff breccia (Tb). Half metre hammer (~~outlined in~~ white arrow) for scale. B) Field photo
953 displaying a ~0.5m thick exposure of thinly bedded, well-sorted, ash, and a lapilli tuff (Lt_2)
954 interbedded within massive lapilli tuff (Lt_1). One metre hammer for scale. C) Field photo
955 showing ~10 m wide and ~4 m thick exposure of moderately to poorly sorted, locally spatter
956 dominated, lapilli tuff (Lt_3). One metre hammer for scale. The white box shows the location of
957 the inset displaying fluidal clast surrounded by a vitric ash matrix.
958

959 **Figure 5:** Field photos illustrating the association of pillowed lava (Lpi), peperitic dykes (Ld_1),
960 and enclosing lapilli tuff (Lt_1): A) Photomosaic of ~30 m wide by~ 4 m thick exposure of
961 pillowed lava (Lpi) mingled with massive lapilli tuff (Lt_1). Inset (white box) shows pillowed
962 lobes with a lens of Lt_1. ~~Hammer (1 m~~One metre hammer (white arrow) for scale. B) Annotated
963 version of 5A. Note preserved lenses of Lt_1 within extensive Lpi deposits. C) Field photo
964 showing ~~~5m~~5 m wide and ~~~4m~~4 m deep exposure of "blooming" pillowed lava (Lpi) within
965 massive lapilli tuff (Lt_1). Note a feeder dyke (Ld_1) (white arrow) is visible through the coherent
966 Lpi body. Inset (white box) shows pillowed lava in contact with a lens of Lt_1. D) Annotated
967 version of 5C.
968

969 **Figure 6:** Field photos illustrating the association of pillowed lava (Lpi) with peperites (Pi) and
970 peperitic textures present at Cracked Mountain: A) Photomosaic of ~10 m wide and ~4 m thick
971 exposure volcaniclastic peperite (Pi) formed along the margins of coherent bodies of pillowed
972 lava (Lpi). ~~Human~~Tape measure (white arrow) and human for scale. Inset (white box) shows
973 quench-fragmented peperite bounding Lpi. Marker for scale. B) Annotated version of 6A. C)

974 Example of globular (fluidal) peperite (Pi) texture. Pen for scale. D) Example of blocky peperite
975 (Pi) texture. Pen for scale.
976
977 **Figure 7:** Field photos illustrating the structure and variable clast types found in Cracked
978 Mountain tuff breccias (Tb). A) Massive, ~1.5 m thick, tuff breccia (Tb) dominated by
979 subrounded to blocky lava, overlying massive lapilli tuff (Lt$_1$). Hammer (1 m) for scale. B)
980 Massive, tuff breccia (Tb) dominated by subrounded to blocky lava, with minor, block-sized
981 lapilli tuff lithics (Lt$_1$) (white arrows). C) Rare lithic of pahoehoe (Ls) entrained within tuff
982 breccia (Tb). Hammer (1 m) for scale.
983
984 **Figure 8:** Field photos illustrating pillow and subaerial lavas from Cracked Mountain. A)
985 Stacked sequence of pillow lavas (Lp) (view looking NW at SE base of CM), ~150 m wide and
986 ~40 m thick. White arrows mark approximate edifice basement contact at 1500 m a.s.l. B) Wall
987 of pillow lava (Lp), ~10 m high, exposed on the S margin of the volcano. C) Coherent bulbous
988 pillow lobes (Lp) up to ~0.5 m in diameter. ~~Hammer (1 m~~One metre hammer (white arrow~~)~~) for
989 scale. D) Remnant flow-top of jointed sheet lava (Ls) near the summit of the volcano (~1,600 m
990 a.s.l). Black arrows show granitic erratics and scour marks covering the surface of the lava.
991 Hammer (1 m) for scale.
992
993 **Figure 9:** Photomicrographs showing textures of CM volcaniclastic lithofacies. A-~~DC~~, E, G, and
994 ~~GH~~ are plane-polarized images at 4x magnification with a ~~white~~ 2 mm scale. D and F are from
995 Scanning Electron microscopy (SEM), shown with a 300 μm scale bar. A) Photomicrograph of
996 interstitial pillow lava sediment (Lp) ~~comprised~~composed of coarse, jig-saw fractured, weakly
997 vesiculated glass. B) Photomicrograph of massive, ash, and lapilli tuff (Lt$_1$) showing fine-grain
998 juvenile clasts including microlitic (Mlt), blocky (Bl), and highly vesiculated (Vsc) vitric clasts.
999 The matrix contains a small proportion of intact to fragmented olivine (Ol) and plagioclase
1000 crystals. C) Photomicrograph of massive lapilli tuff (Lt$_1$) showing size range of juvenile vitric
1001 clasts and shapes (i.e. blocky and cuspate). D) SEM photomicrograph of 9C showing both
1002 blocky and highly cuspate vesiculated shapes of fine ash fraction (~ 100 μm). E)
1003 Photomicrograph of massive lapilli tuff (Lt$_1$) showing coarse to fine juvenile clasts and
1004 fragmental crystals olivine and plagioclase. Highly vesiculated vitric clasts are abundant. F)
1005 SEM photomicrograph of 9E showing a highly vesiculated (50-60%) coarse vitric juvenile clast.
1006 G) Photomicrograph of thinly bedded lapilli tuff (Lt$_2$) showing layers of ultra-fine ash separating
1007 layers of coarser, blocky (Bl), and vesiculated (Vsc) vitric clasts. H) Photomicrograph of matrix
1008 material supporting spatter dominated lapilli tuff (Lt$_3$) showing a highly vesiculated, vitric
1009 juvenile lapilli clast within an ash and fine lapilli-sized vitric matrix.
1010
1011 **Figure 10:** Major (XRF) and trace elemental (ICP-MS) compositions for whole-rock samples
1012 (white) and glasses (black) from Cracked Mountain. A) Total alkali (Na$_2$O + K$_2$O) vs Silica
1013 (SiO$_2$) wt. % (TAS) with the classification of Le Bas et. al. (1986) and Irvine and Baragar
1014 (1971). B) Mg# (molar MgO/ (MgO +FeO*)∗100) vs Silica (SiO$_2$) wt. % for Cracked Mountain
1015 volcanics. CM samples not measured with ferric titration use the mean value of Fe 2+/ Σ Fe
1016 =0.7228 (N=7) for CM basalts that were determined. C) Rare Earth Trace Element (REE)
1017 compositions of Cracked Mountain volcanics, normalized to a ~~primitive mantle (P~~
1018 ~~mantle)~~Chondrite after Sun and McDonough (1989).
1019

Figure 11. Stereographic plots of ~~magnetic~~paleomagnetic remanence directions for Cracked Mountain volcano and examples of typical, well-behaved demagnetization data. A) Stereographic plot of mean data from CM Sites 2-9 and their α_{95} (p = 0.05) confidence circles (see Table C1). The mean of sites 2-9 ~~are~~ is shown in red. Geocentric Axial Dipole (GAD) field inclination for sampling latitude is shown with a filled square (see Table C1). Present Earth's Field direction (PEF) is shown with a filled star (see table C1). Site 1 is excluded as it is an outlier (see details in Appendix C) that appears to represent rotation associated with extensional collapse. B) Stereographic plots (left) show magnetization directions after stepwise AF and thermal demagnetization of the Lt_1 sample from Site 2 (~~CMV060A~~CMV015A/B), where the filled circles lie on the lower hemisphere. Precision values, given as the maximum angle of deviation (MAD) are included. Orthogonal plots (right) show horizontal projections as filled circles and vertical projections as open circles. Natural remanent magnetization is shown with a circle and cross. Units are in amperes per metre. Note that AF demagnetization for sample ~~CMV060B~~CMV015A produces more coherent results than does thermal demagnetization. C) Well-behaved stepwise demagnetization data for a dyke (Ld_1) sample collected at Site 6 (CMV029A/B), layout, symbols, and units as 12B. Note, this sample shows identical results for AF and thermal demagnetizations. Based on the results of detailed AF and thermal demagnetization of pilot specimens from each site, AF demagnetization is the preferred treatment.

Figure 12: Schematic model (2x V.E) of volcanic evolution of CM. Stage 1: Explosive phreatomagmatic eruptions, building a subaqueous tephra cone. Stage 2: The sustained intrusion of lava into unconsolidated sediments, and endogenous growth of the edifice. Dykes that breached the margins of the volcanic pile produced pillowed lavas within the englacial lake. Stage 3: Involves the buildup of CM to the level of the englacial lake (or above) and subaerial eruption of lava as well as syn-eruptive debris flows forming deposits of massive tuff breccia. Schematic drainage channels are shown forming through the ice sheet. Stage 4: Post-eruptive, glacial retreat, where the top of the edifice is scoured off. Additionally, the removal of glacially confined margins causes extensional, gravity-driven stress on of the overs steeped volcanic successions, causing cracks to form and partial edifice collapse.

Figure 13: Paleoclimate glacial reconstruction at the time of Cracked Mountain eruption, ~401 ka. A) Hillshade DEM for CM map area overlain showing the dispersal of glacial ice. We use the approximate summit of CM (~1650 m a.s.l) as the minimum height at which glacial ice is reached. All regions below 1650 m are shown in light blue (i.e. ice) and all regions above 1650 m are shown in brown. CM edifice is shown in green within a schematic englacial lake. B) Undivided N-S (A-A') and E-W (B'-B) cross-sections for CM, shown at no VE. Volcanic rocks (green) overlie basement (pink) above steep valleys to the N (Meager Creek) and W (Elaho Valley). Schematic glacier ice is shown confining CM with an englacial lake forming around the volcano. The minimum thickness of the englacial lake is ~250 m estimated from the total thickness of the edifice. C) Schematic 3D DEM is shown for the CM map area. The same colours and symbols were used in ~~14A~~13A. Glacial ice is shown reaching minimum elevations of 1650 m a.s.l. with a minimum thickness of ~850 m based on the elevation of Meager Creek. Schematic drainage channels are shown based on the physiographic setting of the edifice.

1065 **Figure 14:** Mid to late Pleistocene Marine $\delta^{18}O$ ($\%_{oo}$) isotope record (MIS), modified from
1066 Lisiecki and Raymo (2005) showing fluctuations (and numbered stages) in global ice from,
1067 where higher $\delta^{18}O$ represents periods of more global ice and lower $\delta^{18}O$ represents periods of
1068 lower global ice. The vertical axis is a record of time (ka) with magnetic pole orientations shown
1069 through the Pleistocene. Dark bars are times of normal polarity and white bars are times of pole
1070 reversal. The dashed box indicates the blow-up portion of the MIS from 250-600 ka. The
1071 Cracked Mountain plateau age of 401.6 ± 38.1 ka is plotted (grey shaded) on the blow-up MIS
1072 portion, representing times from the waning of MIS 12 through MIS 11. The preferred age of
1073 Cracked Mountain is indicated with a dashed line at ~425 ka.
1074
1075

1076

Highlights:

- o Cracked Mountain is Pleistocene (~425 ka) tuya in Canadian Cascades

- o Lithofacies indicate explosive onset to subaqueous monogenetic eruption
- o Eruption was within an englacial lake having (depth of 250 m; volume of 0.36 km^3)
- o Glaciovolcanic record implies regionally > 850 m thick ice sheet at ~425 ka

Table

Table 1. Codes, descriptions, approximate edifice volume, and interpretations of Cracked Mountain volcanic lithofacies.

|	Facies Code	Vol. %	Description	Interpretation	Figs.
Volcaniclastic	Lt_1	25	Lapilli Tuff: Yellow to grey; massive to crudely bedded, monolithic, moderately to well sorted, and matrix-supported; clasts comprise 10-30% of the unit, with ~10-25% lapilli and >5% blocks; ~20-50% of clasts are glassy, highly vesiculated juveniles, with all other clasts being dense lava lithics; dense clasts are olivine and plagioclase porphyritic, Pl (5-10%) Ol (5%) with < 50% showing chilled margins.; matrix material is yellow-orange ash and fine lapilli, comprised of ultra-fine (~5%), blocky (~60%), and cuspate (~30-35%) vitric juveniles; matrix contains intact to fragmented crystals, Pl (5-10% 0.5-2 mm) and Ol (5-10% 0.1-1 mm); lapilli tuff is stratigraphically lowest throughout the edifice.	Subaqueous pyroclastic density currents are derived from Surtseyan tephra cone buildup from the onset of the eruption.	2, 4, 5, 7
	Lt_2	3	Lapilli Tuff: Yellow to grey; thinly bedded, monolithic, moderately to well sorted, and matrix-supported; clasts comprise >10% of the deposit, with 100% being fine lapilli; ~50% of clasts are highly vesiculated vitric juveniles, and ~50% dense basalt lithics; dense lithics are olivine and plagioclase porphyritic to microlitic, Pl (5-10%) Ol (5%); matrix material is yellow ash, comprised of ultra-fine (~10-15%), blocky (~70%), and cuspate (15-20%) vitric juveniles; matrix contains intact to fragmented crystals, Pl (5-10% 0.5-2 mm) and Ol (5-10% 0.1-1 mm).	Subaqueous low density (surge) deposits during the phreatomagmatic buildup of the edifice.	2, 4
	Lt_3	1	Lapilli Tuff: Grey; massive, monolithic, poorly sorted, and matrix-supported; clasts comprise ~20-40% of the deposit, with ~10-15% lapilli and ~20% block; ~50% of clasts are highly vesiculated, fluidal to blocky, spatter juveniles, and ~50% dense basalt lithics; clasts are olivine and plagioclase porphyritic, Pl (5-10%) Ol (5%); the matrix grey, well-sorted, fine lapilli and ash, comprised of ultra-fine (~5%), blocky (~50), and cuspate (~45%) vitric juveniles; matrix contains intact to fragmented crystals, Pl (5-10% 0.5-2 mm) and Ol (5-10% 0.1-1 mm).	Shallow subaqueous to subaerial lava fountaining during the phreatomagmatic buildup of the edifice.	2, 4

	Facies Code	Vol. %	Description	Interpretation	Figs.
Volcaniclastic	Pi	3	Peperite: Yellow to grey; massive, monolithic, moderately sorted, matrix to clast supported; clast shapes range from globular to blocky, clasts comprise <50% of the deposit, with ~40% lapilli and ~10% blocks; clasts ubiquitously show chilled margins and display jig-saw fracture patterns; clasts are vitric and highly vesicular, up to 50-60%, and are olivine and plagioclase porphyritic, (Pl 5-10%, Ol 5%); matrix material is yellow-orange ash, comprised of ultra-fine (~5-10%), blocky (~60%), cuspate (~30%) vitric juveniles; Pi is stratigraphically adjoining Lpi throughout the edifice.	Quenched volcaniclastic material formed along with bodies of (Lpi) by fuel coolant reactions within water-saturated, unconsolidated lapilli tuffs (Lt1).	2, 6
	Tb	16	Tuff Breccia: Yellow to grey; massive, monolithic, moderately to poorly sorted, and clast supported; clasts are subrounded to angular, ranging from 65-70% coarse lapilli and ~5-10% blocks; 10-30% of components are subrounded pillow lithics (Lpi, Lp), ~60-70% are dense to highly vesiculated blocky lava (Ls), and ~1-2% are lapilli to block-sized rounded lapilli tuff lithic (Lt1); all coherent clasts are olivine and plagioclase porphyritic, Pl (5-10%) Ol (5%); matrix material is yellow-orange ash and lapilli, comprised of ultra-fine (~5%), dense (~60%), and cuspate (~35%) vitric juveniles; breccia blankets and fills in topography throughout the edifice.	Near and proximal vent syn- and post-depositional debris flow avalanches in subaqueous and subaerial settings.	2, 7
Coherent	Lp	20	Pillowed lava: Dark grey to black; intact to fragmented, rounded to oblong lobes, with individual diameters ranging from 0.2 to 0.5 m; vitric rims up to 1 cm are common; pillows are moderate to highly vesicular (50-65%) and commonly display concentric vesicle layers in cross-section; pillows are hypocrystalline, and olivine and plagioclase porphyritic, Pl (10-15%, 0.5-3 mm), Ol (5-10%, 0.1-1 mm); rare augite phenocrysts are observed in thin-section, Cpx (1-2%, 0.1-1 mm) pillows contain yellow-orange interstitial quench fragmented ash and lapilli between adjacent lobes.	Subaqueous extrusion of lava at moderate to low eruption rates within the ice-confined glacial lake.	2, 8

	Facies Code	Vol. %	Description	Interpretation	Figs.
Coherent	Lpi	20	Pillowed lava: Dark grey to black; domains of intact to dispersed, subrounded to oblong pillowed lobes, with individual diameters ranging from 0.2 to 0.5 m; vitric rims up to 1 cm are common; lobes are moderate to highly vesicular (50-65%) and commonly display concentric vesicle layers in cross-section; lobes are hypocrystalline, and olivine and plagioclase porphyritic, Pl (10-15%, 0.5-3 mm), Ol (5-10%, 0.1-1 mm); lobes are mingled within moderately to highly palagonitized lapilli tuffs. Corrugated vitric rinds cover lobes and tubes in some exposures.	The subaqueous intrusion of lava into unconsolidated, water-saturated volcaniclastic sediments (Lt1).	2, 5
	Ls	2	Jointed lava: Dark grey to black; columnar to blocky jointed, columns range from 0.2 to 0.5 m in diameter; lavas are dense, with moderate vesicularity (~20-30%); lavas are holocrystalline and are olivine and plagioclase porphyritic, Pl (10-15%, 0.5-3 mm), Ol (5-10%, 0.1-1 mm); rare augite phenocrysts are observed in thin-section, Cpx (1-2%, 0.1-1 mm), little to no interstitial sediments are present between jointed lavas. Outcrops are poorly preserved and show signs of glacial scouring.	Subaerial extrusion of lava at moderate to low eruption rates, at elevations above englacial lake level.	2, 8
	Ld₁	5	Dykes: Dark grey to black; subvertical to curved, thickness ranges from 0.5 to 1.5 m; dyke margins are poorly defined to pillowed margins; dykes are moderately vesicular (~20-40%); dykes are holocrystalline, and are olivine, plagioclase (glomero) porphyritic, Pl (10-15%, 0.5-3 mm) Ol (5-10%, 0.1-1mm)	Early-stage intrusions into unlithified Lt1 coinciding with emplacement of coherent lavas (Lpi, Lp).	2, 5
	Ld₂	5	Dykes: Medium to dark grey; subvertical and jointed, thickness ranges from 0.5 to 3 m; dyke margins are well defined with laterally pointing small columnar joints; dykes are moderately vesicular (~20-40%); dykes are holocrystalline and are olivine, plagioclase, and augite (glomero) porphyritic, Pl (10-15%, 0.5-3 mm) Ol (10%, 0.1-1mm) Cpx (1-2%, 0.1-1 mm); dykes contain minor crustal xenoliths.	Late-stage intrusions postdating lithification of Lt1 and growth of edifice.	2

Table 2. Summary of distribution, descriptions, and interpretations of lithofacies associations at Cracked Mountain

Association	Lithofacies present	Stratigraphic relationships	Distribution	Interpretation	Figs.
(A)	Lt1, Lpi, Ld1	Lt1 is intruded by Ld1 and mingled with Lpi; Lpi blooms away from pillowed margins of Ld1	Ubiquitous in crack exposures throughout mid and upper elevations of the edifice; small localized outcrops at the base of edifice near basement contact	Lt1 was deposited in a water-rich environment and was intruded by Ld1 while it was still unconsolidated; as the Ld1 entered the saturated unconsolidated Lt1, the injecting magma pillowed due to water-rich environments and disaggregated due to reduced pressure	5
(B)	Lpi, Pi	Pi is interbedded and adjacent to coherent Lpi, at times forming gradational contacts	Pi is exposed at the surface in small outcroppings in the central and high elevations of the edifice but is commonly observed within cracks exposures across the whole mountain	Pi formed along the margins of larger pods of Lpi where the highly saturated host sediment caused quenching and disaggregation of magma from the margins of the host intrusion.	6
(C)	Ls, Tb, Lp, Lpi, Lt1-3	Ls and Tb overly Lp, Lpi, and Lt1-3; Lithics of Ls, Lp, Lpi, and Lt1 are entrained within Tb	Ls outcrops sporadically as small remnant outcrops near the present-day summit of the edifice, Tb blankets and fills topography, extending from the central summit toward the outer margins of the edifice	Ls formed subaerially as the englacial lake level dropped below the elevation of erupting magma; Tb formed as lava piles and slopes collapsed from over steepening and/or oversaturation, spreading out as mass flow breccias across the highest levels of volcanic stratigraphy; near the summit and central vent, explosive bursts ejected ballistics of subrounded Lt1 which are entrained in Tb	7, 8
(D)	Ld1 Ld2, Ls, Tb, Lp, Lpi, Pi, Lt1-3	Ld2 cuts through all other lithofacies.	Ld2 is present in the central vent area and high elevations of the edifice as well as seen cutting along the stacked lava at the edges of the mountain	Ld2 represent the latest stage of the Cracked Mountain eruptions; the other lithofacies were already cooled and lithified prior to these late-stage intrusions	

Table 3. Representative whole-rock major (wt. %) and rare earth (ppm) element compositions of Cracked Mountain volcanic rocks analysed by X-ray fluorescence and ICP-MS, respectively. Analytical precision (2s) on major and trace elements based on replicates is reported in brackets.

Abstract

1

2 Cracked Mountain (CM) is a basaltic volcano within the northern extension of the Cascade

3 volcanic arc into southwest, British Columbia, Canada (i.e. Garibaldi Volcanic Belt) and is dated

4 at 401 ± 38 ka (^{40}Ar/^{39}Ar). The edifice covers an area of ~1.5 km^2 and has a volume of 0.18 km^3.

5 The volcano features steep margins with local relief of ~250 m (1,650 m a.s.l), is dissected by

6 abundant 0.5 to ~20 m wide extensional cracks with depths up to 30 m, and has a highly eroded

7 top. The edifice is dominated by massive to poorly stratified, moderately to pervasively

8 palagonitized lapilli tuffs, comprising vitric fine ash to lapilli. Juvenile pyroclasts have blocky to

9 highly vesiculated shapes consistent with a phreatomagmatic (i.e. explosive) origin. The lapilli

10 tuffs are intruded by and mingled with coherent to disaggregated lobes of peperitic pillowed

11 lavas. Contacts between lapilli tuff and peperitic pillowed lava show soft-sediment deformation

12 and in-situ quench-fragmentation indicating that the tephra was both unconsolidated and water-

13 saturated at the time of intrusion. Local stacks of pillow lava are found on the margins of the

14 edifice. More than fifty, 0.5 to 3 m wide dykes intrude CM stratigraphy and display, either,

15 peperitic pillowed margins or sharp, chilled margins and columnar-jointing. Measurements of

16 paleomagnetic directions (9 sites) were made for all CM lithofacies and record a single-pole

17 direction indicating a single monogenetic eruption. A glaciovolcanic origin is strongly suggested

18 by the abundant subaqueous lithofacies (i.e. palagonitized tephra, pillows, peperites) and the

19 physiographic setting of the edifice which is well above any drainage that could sustain a

20 standing body of water. The elevation of CM and depth of surrounding valleys indicate syn-

21 eruptive confinement by a paleo-ice sheet that was ≥ 850 m thick. The edifice shape, size, and

22 surrounding topography suggest a 'leaky' paleolake system capable of supporting ~0.36 km^3 of

23 water. The glaciovolcanic origin and the absolute (^{40}Ar/^{39}Ar) age of CM represent an important

24 record of the Cordilleran Ice sheet (CIS) in southwestern BC during the mid-Pleistocene.

1. Introduction

The Garibaldi Volcanic Belt (GVB) is the northern segment of the Cascade Volcanic Arc (Roddick and Souther, 1987; Green et al., 1988; Hildreth, 2007). GVB volcanic deposits range from Pleistocene to Holocene in age and result from subduction of the Juan de Fuca plate beneath the North American Plate (Roddick and Souther, 1987; Green et al., 1988; Hildreth, 2007). Southwest British Columbia has a protracted history of multiple glaciations, with cycles of advancing and retreating cordilleran ice sheets throughout the Pleistocene (Clague, 2009; Clague and Ward, 2011). As a result, the GVB hosts numerous glaciovolcanic landforms. Prior studies concerning glaciovolcanism have focused on the Mount Garibaldi volcanic field (e.g., Mathews, 1952; Wilson et al., 2019), the Mount Cayley volcanic field (e.g., Kelman et al., 2002; Kelman, 2005), the Mount Meager volcanic complex (MMVC) (e.g., Wilson and Russell, 2017, 2018), the Salal Glacier volcanic complex (e.g., Lawrence et al., 1984; Wilson and Russell, 2018), and the Bridge River volcanic field (e.g., Roddick and Souther, 1987; Wilson and Russell, 2018).

Cracked Mountain is a basaltic volcano situated on the southern flank of the MMVC and originally identified by Read (1979) as part of the Mosaic Assemblage (i.e., undivided, Pleistocene aged, basalts within the MMVC). Here, we present a new dataset including a map of volcanic lithofacies, petrographic and geochemical characteristics of the deposits, geochronometric ($^{40}Ar/^{39}Ar$) age estimates, and paleomagnetic directions of all lithofacies. Collectively, these data inform on the physical volcanological evolution of the Cracked Mountain (CM) volcano. Our analysis shows CM to have a glaciovolcanic origin (Kelman et al., 2002; Smellie, 2007; Edwards et al., 2009) involving sustained eruption within an englacial lake. The lithofacies and their stratigraphic relationships indicate an explosive onset to the eruption dominated by phreatomagmatic activity that transitioned to effusive activity expressed by intrusions and lavas. We use the geometry of the CM edifice (i.e. shape and size) and the distribution of lithofacies to reconstruct the eruptive history of the glaciovolcanic edifice and to constrain the thickness and distribution of the enclosing ice sheet. Our findings contribute to a larger story of glaciovolcanism within the GVB and paleoclimate reconstructions for SW British Columbia.

2. Geological Background

The Mount Meager volcanic complex is situated 160 km north of Vancouver in SW British Columbia (Fig. 1) and is one of eight major centres and volcanic fields comprising the GVB (Fig. 1A). Recent GVB geochemical and petrological studies show increases in melt alkalinity and a decrease in slab-derived signatures moving northward in the GVB (Green and Sinha, 2004; Mullen and Weis, 2013). In particular, the MMVC, Salal Glacier volcanic complex, and Bridge River volcanic field show a heightened primitive signature compared to the southward GVB and the High Cascade volcanoes. These findings suggest that the Nootka Fault, located Northwest of the Bridge River cones (Fig.1A), may mark the terminus of the Juan de Fuca subduction where a window between the Juan de Fuca and Northward Explorer plate allows upwelling of asthenospheric melts under the northernmost GVB centres (Mullen and Weis, 2013).

The MMVC (Fig. 1B) contains Pleistocene to Holocene basalt to rhyolite overlying basement igneous and metamorphic rocks of the Coastal Plutonic complex (Fig 1B) (Woodsworth, 1977; Read, 1979; Green et al., 1988). The MMVC is also host to the youngest GVB eruptive deposits, namely the 2350 B.P. Pebble Creek formation (Hickson et al., 1999; Stewart et al., 2008). Intermediate to felsic lavas are dominant within the Mount Meager Massif, however, localized mafic centres are present in the north (Lillooet Ridge and River), west (Mosaic Ridge), and southwest (Cracked Mountain and Elaho Valley) regions of the volcanic complex (Fig. 1B) (Read, 1979, 1990; Harris and Russell, 2021). The ages of the Mosaic Ridge basalts and Elaho Valley basaltic andesites are ~90 and 140 ka respectively (Woodsworth, 1977; Green et al., 1988).

3. Cracked Mountain Physiography and Morphology

The Cracked Mountain volcano unconformably overlies basement granodiorite (Bg) and schist (Bs) of the Gambier and Cadwallader Groups respectively (Fig. 2A) (Read, 1979). The volcanic deposits form a slightly asymmetric, NE-SW trending ~250 m thick ridge that is ~1,300 m long and ~1,000 m wide covering an area of ~1.5 km^2 and having a present-day volume of ~0.18 km^3. The summit of CM rises to 1,650 m above sea level (a.s.l.) and the margins reach elevations as low as 1,250 m (Fig. 2A). CM is surrounded by steep valleys of the Meager Creek and Elaho River tributaries to the north and west respectively (Fig. 3). Extensional cracks dissect

4

94 the entirety of CM (Figs. 2A; 3B), ranging from 0.5 to > 20 m in width and up to 30 m in depth.

95 The fractures form parallel clusters that commonly trend perpendicular to the downslope

96 direction. All CM lithofacies are offset and displaced by cracks. No glacial deposits (i.e. till,

97 erratics) are found within cracks, suggesting a post-eruptive and post-glacial origin.

98   The shape and surface features of CM show evidence of glacial enveloping and scouring.

99 The present-day surface is littered with cobble to boulder-sized granitic erratics and some

100 locations have been smoothed and striated in a SW direction. These findings show that post-

101 eruption Cordilleran Ice Sheets have reached elevations greater than the summit of CM. The

102 margins of CM are cliffs up to 40 m high, which is unusually thick for basaltic lava (e.g.,

103 Edwards et al., 2015). We interpret this morphology to be a result of syn-eruptive glacial

104 confinement and subsequent erosion. There is no evidence of ice-abutment in the form of

105 laterally facing, hackly, or irregular jointed lavas (e.g., Lescinsky and Fink, 2000; Kelman et al.,

106 2002) suggesting that the outermost CM margins result from post-eruptive glacial erosion rather

107 than reflecting primary lava-ice contact surfaces.

108

109 **4. Volcanic Lithofacies**

110   We recognize ten CM lithofacies (Table 1) that include, both, volcaniclastic and coherent

111 lithofacies. All volcanic deposits are olivine and plagioclase porphyritic and differ only in their

112 groundmass textures ranging from holocrystalline, hypocrystalline, and quenched. The

113 terminology used to describe grain size and componentry of volcaniclastic rocks is after White

114 and Houghton (2006).

115

116 4.1 Volcaniclastic

117   CM lapilli tuffs (Lt_{1-2}) (Table 1) form the stratigraphically lowest (Fig. 2B) lithofacies.

118 Observed thicknesses range from 0.5 m to < 6 m. Lt_1 is massive, moderately- to poorly sorted,

119 and is observed throughout the CM edifice from its base to its summit (Fig. 2; 4A). Lt_1 is

120 composed of dense and blocky to highly vesiculated and cuspate vitric juveniles and contains 5-

121 35% lapilli-sized clasts supported in a vitric ash matrix. Lt_1 is commonly intruded by dykes (Ld_{1-}

122 $_2$) and mingled with peperitic lobes (Lpi; Table 1) (Fig. 5). In some locations, soft-sediment

123 deformation of Lt_1, in the form of squeeze-up pipes, is observed. Lt_2 outcrops in the SE and N

124 sections of CM and, by comparison, are thinly bedded, well-sorted (Fig. 4B). Beds of ultra-fine

125 ash are up to 5 cm thick and dip shallowly in the downslope direction. In some outcrops,

126 microfractures offset laminated beds, and truncated and shallow cross-beds are also observed. Lt_2

127 is commonly observed as 1-2 m layers within thicker, massive Lt_1 exposures (Fig. 2B; 4B) and

128 displays fining upward grain sizes. Lt_3 are locally stratified as defined by accumulations of lapilli

129 and bomb-sized, fluidal to blocky, vesiculated (<60%) spatter clasts (Fig. 4C). The clasts are

130 supported by a well-sorted, vitric ash matrix. Two small outcrops of Lt_3 are located at upper

131 elevations (i.e. high in stratigraphy) in the central and NE sections of the CM.

132   Peperite (Pi) deposits, as defined by White et al., (2000) and Skilling et al., (2002), are

133 volcaniclastic deposits resulting from the mingling of magma with wet, unconsolidated

134 sediments. At CM, peperites occur as fragmented, globular to blocky components of vitric basalt

135 supported by ash and lapilli tuff matrix (Figs. 2B; 6). Peperite deposits are distributed along the

136 margins of the peperitic intrusive bodies (Lpi). We distinguish lithofacies Pi from Lpi (Table 1)

137 as volcaniclastic and coherent, respectively. The thickness of peperites varies from a few cm to

138 2-3 m away from the margins of Lpi. Peperites rarely outcrop at the present-day CM surface but

139 are commonly exposed in cracks at all locations of the volcano.

140   Tuff breccias (Tb) blanket much of the topography in the central and north regions, are

141 the dominant map unit (Fig. 2), and obscure stratigraphically older volcanic lithofacies. At higher

142 elevations, tuff breccias form thin 1-2 m-thick deposits that progressively thicken (<10 m)

143 downslope (Fig. 7). Tuff breccias are massive and clast-supported, featuring monolithic lapilli-to

144 block-sized lithic components. These lithics are olivine-and-plagioclase porphyritic lava

145 fragments of Lpi, Ls, and Lp, where ~30-40% show rounded chilled margins. Minor yellow ash-

146 sized interstitial sediment is present between breccia clasts. Rarely, block and lapilli-sized,

147 rounded Lt_1 lithics are present (Fig. 7B).

148

149 4.2 Coherent

150   The peperitic pillowed lava unit (Lpi) (Table 1) comprises coherent, mingled lavas that

151 intrude volcaniclastic deposits (Lt) across all elevations and locations of the edifice (Fig. 2). Lpi

152 is a mappable unit distinct from coherent pillow lavas (Lp; Table 1) formed through subaqueous

153 effusion. The Lpi unit occurs where magma has been injected into water-saturated sediments and

154 forms massive globular bodies up to 15-20 m across and 10-15 m high, comprising chilled,

155 subrounded lobes (Fig. 5A and B). Additionally, Lpi is often associated with 'blooming' dykes

6

156 (Ld$_1$) (Fig. 5C) that transition from ~0.5-1 m wide intrusions into <5 m wide, "pillowed" masses.

157 Since Lpi intrudes and pillows into lapilli tuff (Lt) (i.e. host sediments) we interpret these

158 lithofacies to be 'peperitic' intrusions, after White and Houghton (2006).

159   Pillow lava deposits (Lp) (Table 1), makeup ~20% of the edifice, and are the dominant

160 lithofacies exposed at the edges of CM (Fig. 2). Pillow lava outcrops at the present-day, high

161 elevations of CM (Figs. 2A) as 1-3 m thick piles and increases to ~ 10-40 m thick along the cliffs

162 at the outer edges of the volcano (Figs. 2B; 8A and B). Individual pillows are bulbous, with

163 diameters up to 50 cm (Fig. 8C). Interstitial quench-fragmented vitric sediment fills void spaces

164 between intact pillows in some outcrops (Fig. 9A). Large radial columnar jointed pods up to 3 m

165 in diameter make up a lesser amount of the lithofacies. Stratigraphically, Lp is overlain by tuff

166 breccia (Tb), is cut by dykes (Ld$_2$), and is observed to overlie outcroppings of lapilli tuff (Lt$_1$) at

167 the base of the edifice (Fig. 2B).

168   Blocky and columnar jointed remnants of sheet lava (Ls) (Table 1) are preserved at the

169 highest elevations of CM near the central and eastern regions (Fig. 2A). Sheet lava outcrops are

170 small, ranging from ~10-30 m across, and 1-2.5 m thick. The sheet lavas have coarse columnar

171 joints up to 0.4 m in diameter and occur at the present-day surface of CM. The tops of the sheet

172 lavas are scoured by SW trending glacial striae and covered with erratics (Fig 8D).

173   Over 50 dykes (Ld$_{1-2}$) intrude the CM volcano (Fig 2A). The dykes are predominantly

174 subvertical and have widths ranging from 0.5 to 3 m in width and up to 100 m in length. The

175 dominant trends of the dykes strike E-NE and W-NW. Dykes were divided into two groups

176 based on their margins: 1) Ld$_1$ (Table 1) have poorly defined, glassy, pillowed, or peperitic

177 margins where they contact bodies of Lpi (Fig. 5C), and 2) Ld$_2$ (Table 1) have sharp, chilled, and

178 columnar jointed margins where they intrude all other lithofacies. Ld$_1$ is prevalent in the central

179 and high elevations of the edifice and is best exposed through extensional cracks. Ld$_2$ outcrop

180 sporadically in the central high elevations of CM, as well as, along the eastern margin of the

181 edifice where they intrude subvertically stacked piles of Lp.

182

5. Lithofacies associations

184   The topmost portion of CM edifice and uppermost stratigraphic units are heavily eroded

185 which precludes us from identifying the precise location and nature (e.g., fissure, cone, etc.) of

186 the vent. However, we expect that the vent was near the present-day summit (elev. ~1580 m)

7

187   where, within a 100 m radius, we find a multitude (~10) of cross-cutting dykes intersecting the

188   upper surface of the edifice. The volcano is volumetrically dominated by subaqueous style

189   lithofacies that result from and record an explosive onset to the eruption followed by effusion

190   (e.g., pillow lava) and intrusion (e.g., dykes). Furthermore, rather than a simple layer-cake

191   stratigraphy, the CM volcano grew: i) laterally where deposits source from higher elevations and

192   extend to the margins of the edifice, and ii) endogenously by abundant intrusions within the

193   volcaniclastic pile. Based on the detailed stratigraphic relationships described above, we define

194   four main lithofacies associations (A-D) (Table 2).

195   Lithofacies association A comprises Lt_1, Lpi, and Ld_1 (Table 2). Lt_1 is intruded by Lpi

196   and Ld_1 at all elevations of the edifice, including exposures at the base of CM (Figs. 2B; 5). Ld_1

197   is observed to be in genetic relation to Lpi (Fig. 5C). Lt_1 outcrops at all elevations of CM, and

198   the deposits are pervasively palagonitized and lithified (Stroncik and Schmincke, 2002). The

199   mingling of Lpi within Lt_1 and examples of soft-sediment deformation indicate that Lt_1 was

200   saturated and unconsolidated at the time of intrusion. Additionally, the margins of Ld_1 are often

201   poorly defined and pillowed, further suggesting a saturated slurry-like host rather than a cooled

202   and lithified host at the time of intrusion. Lastly, Ld_1 is often seen tangential to 'blooming' Lpi,

203   suggesting that these two intrusive bodies are temporally related. Further petrographic

204   similarities (i.e. olivine and plagioclase phenocrysts) substantiate a co-genetic relationship

205   between Lpi and Ld_1. This lithofacies association reveals that unconsolidated ash and lapilli were

206   intruded by peperitic bodies, processes that require a water-saturated eruptive environment.

207   These stratigraphic relations imply an age succession of $Lt_1 > Lpi \geq Ld_1$.

208   Lithofacies association B comprises Lpi and Pi (Table 2); at CM peperite deposits (Pi)

209   are always spatially associated with masses of intrusive pillow lava (i.e. Lpi; Fig. 6). We

210   interpret these occurrences as fuel-coolant interactions (FCI) where the sudden contact of hot

211   magma (e.g., fuel) with cold, saturated sediment (e.g., coolant) generates a vapour film around

212   the intruding body (i.e. Lpi) (Doyle, 2000; Hooten and Ort, 2002; Martin and Németh, 2007).

213   Within the vapour films, instabilities may arise, causing local phreatomagmatic fragmentation

214   along the borders of the intrusion. Regions that experienced more stable vapour films result in

215   globular peperite texture (Fig. 6C) while areas with less film stability produce blocky peperite

216   textures (Figs. 6D) (Martin and Németh, 2007). Most peperite deposits form along the margins

8

217 of syn-volcanic intrusions. The field relations for Lpi and Pi show a contemporaneous origin,

218 with both lithofacies forming as a result of intrusion into wet, unconsolidated lapilli tuffs.

219   Lithofacies association C comprises Tb, Ls, Lp, Lpi, and Lt (Table 2). The tuff breccia

220 (Tb) blankets the upper surface of CM and contains a large proportion (<50%) of sheet lava (Ls)

221 lithics, as well as moderate (30-40%) subrounded lithics of pillowed lava (Lp and Lpi), and

222 minor (>5%) subrounded blocks of Lt (Fig 7). The high volume of Ls lithics entrained within the

223 widespread tuff breccias is our best line of evidence that the sheet lavas preserved at higher

224 elevations were originally more extensive and volumetrically abundant. Post-eruptive erosion

225 (i.e. glacier erratics and scour marks; Fig. 8D) and collapse (i.e. extensive network of extensional

226 fissures) provide a reasonable explanation for the relatively small remnant outcroppings of the Ls

227 unit. The Tb matrix comprises moderately palagonitized, explosively derived fine ash, quench

228 fragmented ash and lapilli, and coherent lapilli lithics. These findings suggest that Tb are syn-

229 eruptive debris flows composed of previously erupted volcanic lithics. The degree of

230 palagonitization alteration throughout the unit suggests subaqueous deposition (Schiffman et al.,

231 2006). The tuff breccias incorporate clasts derived from all other earlier stratigraphic units

232 which, combined with other stratigraphic relationships, suggests the succession

233 $Lt>Lpi\geq Lp>Ls>Tb$.

234   Lithofacies association D comprises Ld_2 with all other CM lithofacies (Table 2). At CM,

235 Ld_2 intrudes through all other lithofacies with sharp, columnar jointed margins, including cross-

236 cutting Ld_1 in select locations. These contact relations indicate that Ld_2 is the latest preserved

237 lithofacies from the CM eruption. This last association suggests a temporal succession of

238 $Lt>Lpi=Pi\geq Ld_1\geq Lp>Ls\geq Tb>Ld_2$.

239

6. Chemistry and Petrography

241 6.1 Petrography

242   Detailed mineral abundances and componentry based on standard polarizing light and

243 scanning electron microscopy (Philips XL30) for all CM volcanic lithofacies are listed in Table

244 1. All coherent CM samples are olivine and plagioclase porphyritic, with glomeroporphyritic

245 clots visible in hand samples. A smaller population of samples also contains phenocrystic augite.

246 Petrographically, the pillowed dykes (Ld_1) have similar mineralogy as found in pillowed (Lpi)

247 and most sheet lavas (Ls). Jointed-dykes (Ld_2) commonly contain phenocrystic augite as do a

9

248 small proportion of pillow lava samples (Lp). Olivine phenocrysts are subhedral and unzoned.

249 Plagioclase phenocrysts are tabular and moderately zoned, with a very minor percentage (>5%)

250 showing sieve textures. When present, augite crystals are subhedral to anhedral.

251   Volcaniclastic samples are distinguished by sorting, grain size, structures, and

252 componentry. Lapilli tuffs (Lt_{1-3}) are composed of monolithic vitric juvenile fine ash and coarse

253 lapilli (Figs. 9B-H) and microlitic tachylyte juvenile pyroclasts (5-30%). Intact to fragmented

254 crystals of olivine and plagioclase are observed within the matrix of Lt_{1-3}. Juvenile shapes range

255 from blocky to highly vesicular (~60-70%) (Figs. 9B-H). Interstitial sediments are observed

256 between coherent Lp clasts but are notably different (i.e. coarse, jig-saw fit clasts compared with

257 Lt_{1-3})(e.g. Fig 9A).

258   Tuff breccia (Tb) componentry is highly variable. Tb is dominated by clasts of basalt

259 (Lpi, Ls, Lp) and contains minor blocks of Lt_1 within a matrix of vitric ash and lapilli. Tb matrix

260 is overall coarser than Lt_{1-3} although still contains abundant blocky and highly vesiculated

261 juveniles.

262

263 6.2 Geochemistry

264   Whole-rock major and trace element geochemical compositions were measured for 26

265 samples by X-ray fluorescence (XRF) analyses of fused discs and by inductively coupled

266 plasma-mass spectroscopy (ICP-MS), respectively. Samples span all CM volcanic lithofacies

267 (i.e. dykes, sheet and pillow lavas, and juvenile vitric-lapilli). Representative compositions of

268 whole rocks and glasses are reported in Table 3; analytical uncertainties are based on replicate

269 analyses done by Acme Analytical Labs Ltd., Vancouver, BC, Canada. A subset of samples was

270 analysed for FeO volumetrically by ALS Canada Ltd., North Vancouver, BC, Canada. Appendix

271 A contains the full data set and additional analytical details.

272   Figure 10A illustrates the chemical diversity of CM samples after Le Bas et. al, 1986

273 classification of volcanic rocks. All CM samples are subalkaline (Irvine and Baragar, 1971) but

274 display moderate spread in SiO_2 (~47-51 wt.%) and Na_2O-K_2O (~3-4 wt. %). The spread in

275 chemistry observed in Fig. 10A correlates with groups of samples having different phenocryst

276 contents. Samples that contain minor modal abundances of augite (in addition to olivine and

277 plagioclase) are typically higher in SiO_2 and Na_2O-K_2O wt. %. However, we find no significant

278 differences in mineralogy or chemical compositions that correlate with the stratigraphic position.

10

279   Fig 10B shows Mg#s (molar MgO/ (MgO +FeO*)∗100) of CM samples with relation to

280   SiO$_2$ wt.%. Within the Cascade arc, volcanic rocks having Mg# > 60 are considered "primitive"

281   indicating limited crustal influence (Green and Harry, 1999; Mullen and Weis, 2013). Our results

282   show CM samples range from Mg# ~55-67 with the majority of samples (~80%) between 60-66.

283   Cracked Mountain rare earth elements (REE) shown in Fig. 10C normalized to chondrite

284   composition after Sun and McDonough (1989). There is little variation in trace element

285   concentrations between samples, including similar anomalies (i.e. positive Eu^{2+}), suggesting a

286   similar mantle source for all CM deposits.

287

288   **7. Geochronometry**

289   7.1 Radiogenic ^{40}Ar /^{39}Ar Results

290   Two CM samples (MH-19-055, 031) were selected for ^{40}Ar /^{39}Ar radiometric dating at

291   the WiscAr Geochronology Labs, University of Wisconsin-Madison, USA. The holocrystalline

292   dyke sample (MH-19-031) proved to be non-measurable because of excess argon trapped in the

293   plagioclase minerals. This is a common issue with basaltic dykes (of young ages) (Brian Jicha,

294   pers. comm. 2021) and with subglacially erupted deposits of all compositions (Clay et al., 2015).

295   The second CM sample (MH-19-055) was collected from the radially jointed interior of a pillow

296   lava outcrop. This sample contained low radiogenic argon but the analysis was still possible

297   through twenty-four heating steps with moderate uncertainty. The results yielded a plateau age of

298   401.6 ± 38.1 ka for crystallization of the groundmass (Fig. B1). Errors are quoted at a 2σ (95%

299   confidence) level and are propagated from all sources except for mass spectrometer sensitivity

300   and the age of the flux monitor. Appendix B contains analytical procedures used and table B1

301   contains complete measured data for heating steps.

302

303   7.2 Paleomagnetic Methods and Results

304   A total of nine sites across the CM edifice were selected for the paleomagnetic study. The

305   sites were chosen to span the entire stratigraphic sequence (i.e. oldest to youngest) and one site

306   (Site 2) was replicated for field and lab reproducibility (Table C1). We preferentially sampled

307   units that cooled quickly, thus locking in the geomagnetic field orientation at the time of

308   emplacement (e.g., Johnson et al., 2008). Efforts were made to sample only intact outcrops

309   thereby avoiding areas suspected of post-emplacement movement. Approximately eight standard

310 2.5-cm-diameter paleomagnetic cores were collected from each site and a minimum of three

311 cores from each outcrop. Each sample was oriented using a magnetic compass, and where

312 possible a sun compass was used in conjunction with magnetic orientations.

313   CM samples were analyzed at the paleomagnetic laboratory at the University of

314 Lethbridge, Alberta. Magnetic susceptibility was determined with a Sapphire Instruments (SI-

315 2B) susceptibility meter. The magnetization of each sample was measured with an AGICO JR-

316 6A spinner magnetometer before demagnetization and again after each level of stepwise

317 demagnetization. CM samples were held in magnetic shields following field collection and

318 between laboratory measurements. All samples were subjected to alternating field (AF)

319 demagnetization, performed using an ASC Scientific D-2000 demagnetizer with a three-axis

320 manual tumbler, and carried out at 10 milli-tesla (mT) steps (up to 200 mT). Thermal

321 demagnetization was carried out at 100, 200, 300, 400, 500, 525, 550, and 580 °C, using an ASC

322 Model TD48 dual-chamber thermal demagnetizer to confirm that alternating field

323 demagnetization was sufficient to resolve the primary remanence. Directions of characteristic

324 magnetization were determined for each sample by principal component analysis (Kirschvink,

325 1980) using Remasoft version 3.0 (Chadima and Hrouda, 2006). Mean directions of

326 characteristic magnetization were calculated for each site and an overall mean was also

327 calculated (Appendix C; Table C1). All samples were subject to stepwise AF demagnetization

328 and principal component analysis and mean directions were calculated from the AF data only.

329   All paleomagnetic samples are normally magnetized (Fig. 11A; Table C1). The mean

330 directions of sites are consistent for eight of nine sites, where all eight sites plot within the

331 uncertainty circle (α_{95}) about the overall mean (N=8) with a declination of 347.3˚ and inclination

332 of 76.6˚, and Fisher precision factor of $k = 351$, $\alpha_{95} = 3.0°$ (Fig. 11A). Typical, well-behaved

333 demagnetization characteristics are shown for samples from Lt_1 and Ld_1 respectively in Figs 11B

334 and C.

335   All paleomagnetic samples produced stable directions of magnetization following

336 stepwise demagnetization. Alternating field demagnetization, applied to all specimens, exhibited

337 linear decay to the origin on orthogonal projections (Fig. 11B and C). The median destructive

338 fields range from 20–80 mT and final directions are often stable up to 200 mT alternating field

339 demagnetization (see CMV015A, Fig. 11B) indicative of single-domain magnetite. Thermal

340 demagnetization showed complete demagnetization at 550 to 580 °C, typical of fine-grained

341 (single domain) magnetite as the magnetic carrier (see CMV029, Fig. 11C). Note that single-

342 domain magnetite is the optimal magnetic mineral and grain size for producing reliable

343 paleomagnetic directions. The magnetic susceptibility values of CM volcanics range from 0.4-

344 1.0 x 10-3 SI (median value of 0.5 x 10-3 SI) for the flows composed of pyroclastic density

345 currents and 2.4-16.4 x 10-3 SI (median value of 4.5 x10-3 SI) for dykes. Mean natural remanent

346 magnetization for CM volcanics is 9.4 A/m (range 0.4–22.0 A/m).

347   The common pole direction obtained for all volcanic units, including the latest dykes,

348 implies a common eruption age indicating a monogenetic origin for the volcano. Furthermore,

349 the data from each site showed no indication of rotation or tilt as the mean direction is within the

350 expected paleosecular variation (see mean of sites 2-9 and GAD inclination for sampling

351 latitude, Fig. 11A, and Table C1). The sole exception was Site 1 (Table C1) where the seven

352 cores record a different mean pole direction compared to the other eight sites (2-9). Site 1 is a

353 lower elevation cliff-side exposure of pillow lava (Lp) on the SE margin of the edifice. Of the

354 seven cores, three can be ascribed to post-emplacement rotation and yield coherent results with a

355 mean declination and inclination of 34.4˚ and 72.9 respectively. The rotation is likely due to

356 partial extensional collapse and, relative to the mean pole direction for the CM edifice, we

357 calculate a downslope rotation of ~12˚E (Fig. C1). This rotation has a calculated maximum

358 crack width of ~20 m which accords well with the observed fissures found on the outer margins

359 of CM (e.g., Fig. 3B).

360

8. Discussion

362 8.1 Explosive Onset to Glaciovolcanic Eruption

363   The lapilli tuff deposits (e.g. Fig 9B-H) comprise coarse to fine ash (>100 μm) particles

364 that are commonly highly vesiculated (<60%). The abundance of fine ash in CM Lt deposits

365 suggests explosive magmatic and/or phreatomagmatic fragmentation (Zimanowski et al., 1991;

366 White and Valentine, 2016; Latutrie and Ross, 2020). The Lt deposits comprise both blocky ash

367 (e.g. Fig 9B) and micro-vesiculated cuspate ash (e.g. Fig 9D and F) suggesting that both

368 phreatomagmatic (external water) and magmatic (internal volatiles) drove the explosive

369 fragmentation processes. We note that blocky juveniles are dominant in Lt_{1-3} suggesting that

370 phreatomagmatic reactions involving glacial meltwater played the largest role in the explosive

371 eruptive style.

372   Based on the overall bedform and textures found in Lt deposits, we assert that the

373   depositional environment was wet and probably (shallow) subaqueous. The massive character

374   and moderate to poor sorting of Lt_1 suggest continuous deposition from a sustained column,

375   rather than periodic explosive pulses which would generate moderately sorted and bedded

376   deposits via elutriation (e.g., White, 1996, 2000). The lack of welding, compaction, or clast

377   imbrication is also consistent with a water-rich intergranular phase (rather than gas) for these

378   pyroclastic density currents (White, 2000; Brand and Clarke, 2009).

379   The thinly bedded, moderate to well sorted, and weakly normally graded Lt_2 is indicative

380   of deposition from dilute pyroclastic density currents (i.e. pyroclastic surge; Fisher and Waters,

381   1970; Brand and Clarke, 2009). These deposits reflect phreatomagmatic explosive pulses that

382   dispersed highly fragmented ash laterally and elutriated through the water column. The shallow

383   dipping cross-bedding preserved in some Lt_2 outcrops (Fig. 4B) is consistent with subaqueous

384   pyroclastic deposits (Moorhouse and White, 2016). The overall lack of well-sorted beds of fine

385   ash, characteristic of thick water column elutriation, makes a shallow subaqueous setting most

386   plausible.

387   Lt_3 contains moderate volumes (20-40 %) of non-welded spatter within moderately to

388   well-sorted ash and lapilli matrix (Fig. 4C). We propose that the Lt_3 deposits record periods of

389   increased magma flux, volatility, and/or a decreased water supply (at the vent), where a

390   strombolian style burst ejected largely vesiculated and fluidal clasts (Latutrie and Ross, 2020).

391   We find that the overall characteristics of the Lt_3 deposits indicate a shallow aqueous to

392   emergent depositional environment. This assertion is based on a lack of bomb sags within these

393   deposits and chilled but not quenched (or pillowed) spatter clasts. The two outcrops of Lt_3 are

394   located at upper elevations of CM, and not observed within lower to middle stratigraphy. Our

395   interpretation is Lt_3 represents localized magmatic generated fallout mixed with

396   phreatomagmatically generated pyroclastic density currents in shallow aqueous to locally drained

397   regions of CM.

398   Explosively derived Lt deposits are present at all elevations of CM (Fig. 2) and comprise

399   ~30% of the entire edifice (Table 1), and excluding intrusions, are closer to 60% of the volcano

400   volume. Our findings indicate that not only was the onset of the CM eruptions explosive but that

401   explosivity was sustained throughout most of the eruption. This explosive-styled eruption makes

402   CM unique within the GVB, being only one of five other identified tephra-dominated

14

403 glaciovolcanic landforms (Wilson and Russell, 2018). We speculate that explosive onsets to

404 glaciovolcanic eruptions may be significantly more common than recognized and underestimated

405 because tephra-dominated landforms are highly susceptible to erosion. We suggest CM's

406 transitional eruptive history, which produced intrusive and effusive coherent lavas, helped create

407 a stronger structure more resistant to glacial erosion.

408   The investigation of Cracked Mountain deposits records a complex sequence of events

409 beyond the initially explosive onset. Our analysis suggests the following conceptual model for

410 the evolution of the CM eruption (Fig. 12):

411 1. An explosive, Surtseyan phase dominated the initial CM eruption, producing a subaqueous

412   tephra cone comprising Lt_1 (Fig. 12A). Our interpretation of this initial phase is detailed

413   above.

414 2. A transition from explosive to effusive (and intrusive) activity (Fig. 12B) is expressed by

415   peperitic dykes (Ld_1) and bodies (Lpi). These intrusions inflate the edifice endogenously and

416   dykes that pierce the margins of the tephra pile form stacks of pillow lavas (Lp) at the

417   margins of the volcano.

418 3. Late-stage intrusions and effusions produce effusive lavas (Ls) and dykes (Ld_2) and

419   associated breccias (Tb), (Fig. 12C). The culmination of the CM eruption is marked by late-

420   stage dyke activity (Ld_2) that cut through all other lithofacies. The paleomagnetic signatures

421   of all CM deposits overlap within one paleomagnetic moment. Thus, the CM eruption taking

422   place from stages 1-3 can be thought of as more or less continuous.

423 The final stage (4) in the CM formation was non-eruptive and characterized by glacial erosion

424 and edifice collapse (Fig. 12D). The timing of glacial retreat is unclear, but the present-day

425 surface features bedrock erratics and scour marks indicating post-eruptive glaciation. The

426 widespread distribution of large extensional fissures and cracks results from the retreat of the

427 enclosing ice sheet which originally buttressed the steep-walled edifice. Glacial erratics are not

428 found within these fissures which may suggest that the edifice was mainly enclosed (and

429 buttressed) by regional and local ice until the Last Glacial Period (i.e. <115 -120 ka).

430

431 8.2 Paleoenvironmental implications

Our mapping and analysis suggest CM is a monogenetic edifice with no evidence for significant time gaps during the eruption. The results of paleomagnetic analyses concur with our field observations that the varying lithofacies were emplaced in one paleomagnetic moment ($\lesssim$ 1,000 years; Turner, 1987; Barletta et al., 2010; Lisé-Pronovost et al., 2013) at 401 ± 38 ka (Fig. B1).

The CM lithofacies (i.e. pillow lavas, palagonitized tuffs, and peperites) indicate a subaqueous eruptive paleoenvironment, however, the edifice is situated at a high elevation in a high relief environment and surrounded by steep-sided deep (~800 m) valleys (Fig. 3). We suggest a glaciovolcanic eruption into a sustained englacial lake of meltwater enclosed by a substantial ice sheet on the basis that there are no obvious physical barriers (i.e. mountains or ridges) to allow for a conventional paleo-lake. The volcanic lithofacies suggest that the englacial lake was sustained throughout the eruption and that the lake surface elevation continued to rise with the growth of the edifice. The CM volcano is best described as a transitional, tephra-dominated, tuya after the descriptive classification of Russell et al., (2014) and its lithofacies associations make it distinct from the classical mafic tuya model (e.g., pillow effusion, hyaloclastites, lava-fed deltas, and capping lava) (Smellie, 2007; Jakobsson and Gudmundsson, 2008; Edwards et al., 2015).

The CM volcanic succession is ~250 m thick and rests on basement rocks at ~1,250 m a.s.l (Fig. 2A). Subaqueous lithofacies outcrop at elevations as high as ~1,650 m a.s.l where they have relief of ~800 m above the major drainages. At the highest elevations of CM (~1,600-1650 m a.s.l), we find small remnant subaerial sheet lavas (Ls) although the abundance of Ls lithics within the thick succession of Tb deposits may suggest that there was much more subaerial lava originally. There are, at least, two scenarios that would explain subaerial capping lavas within the englacial lake environment. The most likely scenarios are that, either, i) the edifice grew and became emergent above the paleolake level to form a classic passage zone defining a maximum lake level (Jones, 1970; Smellie, 2006; Russell et al., 2013; Edwards et al., 2015) or ii) the level of the englacial lake decreased due to subglacial drainage creating a "dry" subaerial environment. In the latter case, post-draining subaerial lavas overlapping the subaqueous lithofacies establish a minimum level of the englacial lake (Smellie, 2006; Skilling, 2009; Russell et al., 2013).

462   There is no direct evidence for a passage zone relationship (i.e. beds of pillow lava

463   breccias or lava fed deltas) so we favour the second scenario involving overlap lavas wherein the

464   elevation of Ls at ~1,650 m defines a minimum level and, thus, a minimum depth of ~250 m for

465   the paleo-englacial lake (Fig 13B). We have used the shape and size of the CM edifice and the

466   surrounding topography to constrain the maximum dimensions and volume of the paleo-

467   englacial lake. The paleo-topography beneath the CM edifice (Figs. 3, 13A) limits the size of the

468   syn-eruptive englacial lake. Relative to the present-day edifice we estimate the lake may have

469   extended <100 m to the south and <300 m to the east but been limited to < 50 m to the north and

470   west by very steep drainages. Assuming an asymmetric shape of 1,800 m long and 1,300 m wide

471   and a maximum depth of 250 m (Fig. 13B) yields a maximum lake volume at ~0.36 km^3. The

472   present-day (i.e. minimum) volume of the CM volcano is ~0.18 km^3 such that the lake could

473   only store < 0.18 km^3 of water (i.e. maximum lake volume – edifice volume). This strongly

474   suggests that throughout the eruption the englacial lake was never fully sealed but was a leaky

475   system where meltwater production and sub-ice drainage were nearly matched (cf. Russell et al.

476   2014). As the eruption waned, melting of the enclosing ice became less efficient and drainage

477   became dominant, leading to a lowering of the lake level to allow for subaerial eruption of lavas

478   (Fig. 12C).

479   To sustain a lake level of 250 m requires a rate of leakage less than the rate of meltwater

480   accumulation and also requires an ice thickness above ~280-300 m to counterbalance the

481   hydrostatic lake pressure (e.g., Tweed and Russell, 1999; Smellie, 2006; Edwards et al., 2015).

482   The surrounding topography features steep drainages with valley floors at ~ 800 m a.s.l. (i.e.

483   Meager Creek and Elaho valley; Figs. 3 and 13). This suggests that the enclosing ice sheet, an

484   earlier (paleo-) incarnation of the Cordilleran Ice Sheet (CIS) at 401 ± 38 ka, was at least 880 m

485   thick. This minimum ice thickness has implications for the distribution of the paleo-CIS and

486   suggests that most of the surrounding landscape was under ice except at the highest elevations

487   (Fig. 13A and C; Clague, 2009; Wilson et al., 2020).

488   The CM age of 401 ± 38 ka coincides with the waning of marine $\delta^{18}O$ isotope stage

489   (MIS) 12 glacial period (~470-425 ka) and the warming period of MIS 11 (~420-375 ka)

490   (Lisiecki and Raymo, 2005) (Fig. 14). The shift in global $\delta^{18}O$ associated with the MIS 12 to 11

491   transition is the largest of all the Pleistocene cycles and signifies rapid global warming (e.g. Fig

492   14; Lisiecki and Raymo, 2005). The ~850 m (or thicker) thickness of the paleo-CIS enclosing the

493 Cracked Mountain volcano is inconsistent with the mid-point of MIS 11 at 400 ka. However, if

494 we accept a slightly older ^{40}Ar /^{39}Ar age of ~425 ka (still within the analytical uncertainty)

495 (Table B1) for the eruption of Cracked Mountain, the age accords well with the global ice period

496 MIS 12 (Lisiecki and Raymo, 2005; Batchelor et al., 2019). Eruption ages for other volcanoes in

497 the GVB are sparse, however, Wilson and Russell (2018) report glaciovolcanic eruptions during

498 MIS 12 within the Mount Cayley volcanic field (Ember Ridge, unpublished age), as well as,

499 subaerial lavas erupting in the Salal glacier field during MIS 11 (Nichols Valley at 405 ka).

500 These additional age constraints, although limited, do support the eruption of Cracked Mountain

501 into an early (late-Pleistocene) incarnation of the CIS within SW British Columbia at ~ 425 ka.

502 We also speculate that at this time, there may have been a large-scale decompression

503 effect on the Earth's crust driven by rapid deglaciation at the end of MIS 12. The link between

504 volcanism and crustal unloading during periods of deglaciation has been modeled throughout the

505 GVB (e.g., Wilson and Russell, 2020) and explored in Icelandic and Andean glaciovolcanic

506 fields (e.g., Carrivick et al., 2009; Guillot and Ponce, 2021). We, therefore, find it entirely

507 feasible that the CIS retreat in SW British Columbia would have triggered magmatic ascent

508 through the unloaded crust, leading to the eruption of the Cracked Mountain volcano (as well as

509 others). Lastly, since records of older glaciation cycles tend to be obscured by younger waxing

510 and waning of ice sheets, our findings at CM provide useful temporal and physical constraints

511 for the CIS extent in SW British Columbia during the mid-Pleistocene.

512

513 **9. Summary**

514 The Garibaldi Volcanic Belt contains many Quaternary glaciovolcanic centres. The study of

515 these volcanoes provides paleoclimatic evidence at the time of the eruptions and contributes to

516 the understanding of magma, ice, and water interactions more generally. Here, we present the

517 first physical volcanological study of Cracked Mountain, a transitional, tephra-dominated tuya.

518 Our findings indicate an initially explosive eruption that later transitioned into intrusive and

519 effusive activity. We characterize the explosivity as dominantly phreatomagmatic, manifested as

520 Surtseyan style eruption in a shallow englacial lake. Peperitic intrusions and pillow lava

521 effusions are the largest coherent units by volume, indicating that subaqueous conditions

522 persisted through the middle and later stages of the eruption. Small remnants of subaerially

523 erupted lavas are preserved at the highest elevations, suggesting that the lake drained periodically

524 in the later stages of the eruption. This claim is supported by our modeling of paleolake

525 dimensions and volumetric capacities. Lastly, our temporal investigation of the eruption

526 concludes that CM was monogenetic, erupting ~425 ka between MIS 11 and 12. We model the

527 localized, mid-Pleistocene CIS as having a minimum thickness of ~850 m, reaching elevations of

528 1,680 m a.s.l or higher.

Figure Captions

Figure 1: Location and geologic setting of Cracked Mountain volcano. A) Map of the Cascade volcanic arc in the USA and Canada (i.e. Garibaldi volcanic belt (GVB)) (modified from Mullen and Weis, 2013; Wilson and Russell, 2017). B) Undivided geological map of MMVC distribution of Mt. Meager volcanic deposits (MV), basement (Bu) throughout the region (Woodsworth, 1977; Read, 1979; Harris and Russell, 2021). The youngest MMVC eruption, 2350 B.P. Pebble Creek Formation (PcF) (Hickson et al., 1999; Stewart et al., 2008) is differentiated from other MMVC volcanics. Cracked Mountain (CM) is situated south of the main MMVC (Wilson and Russell, 2018; Harris and Russell, 2021). Map projection based on Universal Transverse Mercator, Zone 10U North American Datum 1983.

Figure 2: Geology of Cracked Mountain. A) Geologic map showing the distribution of CM volcanic lithofacies. Dyke location and orientations are shown in red; extensional cracks are shown in black. The volcanic edifice unconformably overlies basement granodiorites (Bg) and mica-schists (Bs). White-numbered dots show locations of representative stratigraphic logs (B, C). B) Graphic logs showing volcanic stratigraphy at various locations and elevations within the map area (depicted in Figs. 2A). Lithologies are depicted with various patterns and symbols while corresponding map units are shown in the same colours as Fig. 2A. Red lines shown in map units represent intruding dykes observed within the lithologies of the graphic logs. Map projection based on Universal Transverse Mercator, Zone 10U North American Datum 1983.

Figure 3: Physiographic setting of Cracked Mountain volcano. A) NE-SW oriented Google Earth imagery of Cracked Mountain showing the location of volcanic deposits overlying basement rocks (white-arrows). B) N-S oriented Google Earth imagery of Cracked Mountain (outlined in white), highlighting visible cracks parallel the steep drainages. C) South-West facing DEM hillshade map showing CM volcanics (red shaded outline) situated above present-day Meager Creek and Elaho Valleys.

Figure 4: Field photos displaying bedform structures of CM lapilli tuffs: A) Field photo showing ~2 m thick exposure of massive, moderately sorted ash and lapilli tuff underlying poorly sorted tuff breccia (Tb). Half metre hammer (white arrow) for scale. B) Field photo displaying a ~0.5m thick exposure of thinly bedded, well-sorted, ash, and a lapilli tuff (Lt_2) interbedded within massive lapilli tuff (Lt_1). One metre hammer for scale. C) Field photo showing ~10 m wide and ~4 m thick exposure of moderately to poorly sorted, locally spatter dominated, lapilli tuff (Lt_3). One metre hammer for scale. The white box shows the location of the inset displaying fluidal clast surrounded by a vitric ash matrix.

Figure 5: Field photos illustrating the association of pillowed lava (Lpi), peperitic dykes (Ld_1), and enclosing lapilli tuff (Lt_1): A) Photomosaic of ~30 m wide by~ 4 m thick exposure of pillowed lava (Lpi) mingled with massive lapilli tuff (Lt_1). Inset (white box) shows pillowed

754 lobes with a lens of Lt₁. One metre hammer (white arrow) for scale. B) Annotated version of 5A.
755 Note preserved lenses of Lt₁ within extensive Lpi deposits. C) Field photo showing ~5 m wide
756 and ~4 m deep exposure of "blooming" pillowed lava (Lpi) within massive lapilli tuff (Lt₁). Note
757 a feeder dyke (Ld₁) (white arrow) is visible through the coherent Lpi body. Inset (white box)
758 shows pillowed lava in contact with a lens of Lt₁. D) Annotated version of 5C.
759
760 **Figure 6:** Field photos illustrating the association of pillowed lava (Lpi) with peperites (Pi) and
761 peperitic textures present at Cracked Mountain: A) Photomosaic of ~10 m wide and ~4 m thick
762 exposure volcaniclastic peperite (Pi) formed along the margins of coherent bodies of pillowed
763 lava (Lpi). Tape measure (white arrow) and human for scale. Inset (white box) shows quench-
764 fragmented peperite bounding Lpi. Marker for scale. B) Annotated version of 6A. C) Example of
765 globular (fluidal) peperite (Pi) texture. Pen for scale. D) Example of blocky peperite (Pi) texture.
766 Pen for scale.
767
768 **Figure 7:** Field photos illustrating the structure and variable clast types found in Cracked
769 Mountain tuff breccias (Tb). A) Massive, ~1.5 m thick, tuff breccia (Tb) dominated by
770 subrounded to blocky lava, overlying massive lapilli tuff (Lt₁). Hammer (1 m) for scale. B)
771 Massive, tuff breccia (Tb) dominated by subrounded to blocky lava, with minor, block-sized
772 lapilli tuff lithics (Lt₁) (white arrows). C) Rare lithic of pahoehoe (Ls) entrained within tuff
773 breccia (Tb). Hammer (1 m) for scale.
774
775 **Figure 8:** Field photos illustrating pillow and subaerial lavas from Cracked Mountain. A)
776 Stacked sequence of pillow lavas (Lp) (view looking NW at SE base of CM), ~150 m wide and
777 ~40 m thick. White arrows mark approximate edifice basement contact at 1500 m a.s.l. B) Wall
778 of pillow lava (Lp), ~10 m high, exposed on the S margin of the volcano. C) Coherent bulbous
779 pillow lobes (Lp) up to ~0.5 m in diameter. One metre hammer (white arrow) for scale. D)
780 Remnant flow-top of jointed sheet lava (Ls) near the summit of the volcano (~1,600 m a.s.l.).
781 Black arrows show granitic erratics and scour marks covering the surface of the lava. Hammer (1
782 m) for scale.
783
784 **Figure 9:** Photomicrographs showing textures of CM volcaniclastic lithofacies. A-C, E, G, and
785 H are plane-polarized images at 4x magnification with a 2 mm scale. D and F are from Scanning
786 Electron microscopy (SEM), shown with a 300 μm scale bar. A) Photomicrograph of interstitial
787 pillow lava sediment (Lp) composed of coarse, jig-saw fractured, weakly vesiculated glass. B)
788 Photomicrograph of massive, ash, and lapilli tuff (Lt₁) showing fine-grain juvenile clasts
789 including microlitic (Mlt), blocky (Bl), and highly vesiculated (Vsc) vitric clasts. The matrix
790 contains a small proportion of intact to fragmented olivine (Ol) and plagioclase crystals. C)
791 Photomicrograph of massive lapilli tuff (Lt₁) showing size range of juvenile vitric clasts and
792 shapes (i.e. blocky and cuspate). D) SEM photomicrograph of 9C showing both blocky and
793 highly cuspate vesiculated shapes of fine ash fraction (~ 100 μm). E) Photomicrograph of
794 massive lapilli tuff (Lt₁) showing coarse to fine juvenile clasts and fragmental crystals olivine
795 and plagioclase. Highly vesiculated vitric clasts are abundant. F) SEM photomicrograph of 9E
796 showing a highly vesiculated (50-60%) coarse vitric juvenile clast. G) Photomicrograph of thinly
797 bedded lapilli tuff (Lt₂) showing layers of ultra-fine ash separating layers of coarser, blocky (Bl),
798 and vesiculated (Vsc) vitric clasts. H) Photomicrograph of matrix material supporting spatter

799 dominated lapilli tuff (Lt$_3$) showing a highly vesiculated, vitric juvenile lapilli clast within an ash
800 and fine lapilli-sized vitric matrix.
801
802 **Figure 10:** Major (XRF) and trace elemental (ICP-MS) compositions for whole-rock samples
803 (white) and glasses (black) from Cracked Mountain. A) Total alkali (Na$_2$O + K$_2$O) vs Silica
804 (SiO$_2$) wt. % (TAS) with the classification of Le Bas et. al. (1986) and Irvine and Baragar
805 (1971). B) Mg# (molar MgO/ (MgO +FeO*)*100) vs Silica (SiO$_2$) wt. % for Cracked Mountain
806 volcanics. CM samples not measured with ferric titration use the mean value of Fe 2+/ Σ Fe
807 =0.7228 (N=7) for CM basalts that were determined. C) Rare Earth Trace Element (REE)
808 compositions of Cracked Mountain volcanics, normalized to a Chondrite after Sun and
809 McDonough (1989).
810
811 **Figure 11**. Stereographic plots of paleomagnetic remanence directions for Cracked Mountain
812 volcano and examples of typical, well-behaved demagnetization data. A) Stereographic plot of
813 mean data from CM Sites 2-9 and their α$_{95}$ (p = 0.05) confidence circles (see Table C1). The
814 mean of sites 2-9 is shown in red. Geocentric Axial Dipole (GAD) field inclination for sampling
815 latitude is shown with a filled square (see Table C1). Present Earth's Field direction (PEF) is
816 shown with a filled star (see table C1). Site 1 is excluded as it is an outlier (see details in
817 Appendix C) that appears to represent rotation associated with extensional collapse. B)
818 Stereographic plots (left) show magnetization directions after stepwise AF and thermal
819 demagnetization of the Lt$_1$ sample from Site 2 (CMV015A/B), where the filled circles lie on the
820 lower hemisphere. Precision values, given as the maximum angle of deviation (MAD) are
821 included. Orthogonal plots (right) show horizontal projections as filled circles and vertical
822 projections as open circles. Natural remanent magnetization is shown with a circle and cross.
823 Units are in amperes per metre. Note that AF demagnetization for sample CMV015A produces
824 more coherent results than does thermal demagnetization. C) Well-behaved stepwise
825 demagnetization data for a dyke (Ld$_1$) sample collected at Site 6 (CMV029A/B), layout,
826 symbols, and units as 12B. Note, this sample shows identical results for AF and thermal
827 demagnetizations. Based on the results of detailed AF and thermal demagnetization of pilot
828 specimens from each site, AF demagnetization is the preferred treatment.
829
830 **Figure 12:** Schematic model (2x V.E) of volcanic evolution of CM. Stage 1: Explosive
831 phreatomagmatic eruptions, building a subaqueous tephra cone. Stage 2: The sustained intrusion
832 of lava into unconsolidated sediments, and endogenous growth of the edifice. Dykes that
833 breached the margins of the volcanic pile produced pillowed lavas within the englacial lake.
834 Stage 3: Involves the buildup of CM to the level of the englacial lake (or above) and subaerial
835 eruption of lava as well as syn-eruptive debris flows forming deposits of massive tuff breccia.
836 Schematic drainage channels are shown forming through the ice sheet. Stage 4: Post-eruptive,
837 glacial retreat, where the top of the edifice is scoured off. Additionally, the removal of glacially
838 confined margins causes extensional, gravity-driven stress on of the overs steeped volcanic
839 successions, causing cracks to form and partial edifice collapse.
840
841 **Figure 13:** Paleoclimate glacial reconstruction at the time of Cracked Mountain eruption, ~401
842 ka. A) Hillshade DEM for CM map area overlain showing the dispersal of glacial ice. We use the
843 approximate summit of CM (~1650 m a.s.l) as the minimum height at which glacial ice is
844 reached. All regions below 1650 m are shown in light blue (i.e. ice) and all regions above 1650

27

845   m are shown in brown. CM edifice is shown in green within a schematic englacial lake. B)
846   Undivided N-S (A-A') and E-W (B'-B) cross-sections for CM, shown at no VE. Volcanic rocks
847   (green) overlie basement (pink) above steep valleys to the N (Meager Creek) and W (Elaho
848   Valley). Schematic glacier ice is shown confining CM with an englacial lake forming around the
849   volcano. The minimum thickness of the englacial lake is ~250 m estimated from the total
850   thickness of the edifice. C) Schematic 3D DEM is shown for the CM map area. The same
851   colours and symbols were used in 13A. Glacial ice is shown reaching minimum elevations of
852   1650 m a.s.l. with a minimum thickness of ~850 m based on the elevation of Meager Creek.
853   Schematic drainage channels are shown based on the physiographic setting of the edifice.
854
855   **Figure 14:** Mid to late Pleistocene Marine $\delta^{18}O$ ($^{o}/_{oo}$) isotope record (MIS), modified from
856   Lisiecki and Raymo (2005) showing fluctuations (and numbered stages) in global ice from,
857   where higher $\delta^{18}O$ represents periods of more global ice and lower $\delta^{18}O$ represents periods of
858   lower global ice. The vertical axis is a record of time (ka) with magnetic pole orientations shown
859   through the Pleistocene. Dark bars are times of normal polarity and white bars are times of pole
860   reversal. The dashed box indicates the blow-up portion of the MIS from 250-600 ka. The
861   Cracked Mountain plateau age of 401.6 ± 38.1 ka is plotted (grey shaded) on the blow-up MIS
862   portion, representing times from the waning of MIS 12 through MIS 11. The preferred age of
863   Cracked Mountain is indicated with a dashed line at ~425 ka.
